Physiologic Action and Antidotes of Snake Venom.—Leonard Rogers² states that broadly we may divide venoms into 2 classes: (1) The colubrines, of which the cobra is the best known example—these act mainly by paralyzing the respiratory centers in the medulla, and the motor end-plates of the phrenic nerves, more especially combined with a much less important action on the blood, and (2) the viperine class, which have hitherto been thought to act mainly on the blood, producing intravascular clot, as in Russel viper of India, or loss of coagulation, or hemorrhages, as in the rattlesnake of America. He shows that a still more important and constant action of the viperine class is the production of a paralysis of the central vasomotor centers in the medulla, just as the colubrine class paralyzes the respiratory functions of this part of the nervous system. With regard to the chemic nature of the poisons, he mentions that the venoms contain actively poisonous albumose, and that the viperine class are coagulated and rendered inert at a lower temperature than are the colubrine ones, yet the difference is not absolute. There are connecting links between the 2 classes, as he shows by the venom of one variety of snake; this is the branded krait, whose venom is of mixed colubrine and viperine action. There appears to be a gradation by means of connecting links between the main colubrine and viperine divisions. These are set forth in a table, which likewise represents the action of the venom of each of several varieties upon the nervous system, the blood, and the vasomotor system. [A.B.C.]

Congenital Transposition of the Viscera.—F. C. Studley³ reports the autopsy findings in a case of this condition, diagnosed during life. The patient was a man of 44, weighing 200 pounds. All the thoracic and abdominal organs were transposed, including the colon, except the lungs, which were lobed as in ordinary individuals. The man was right-handed. The heart was greatly hypertrophied, weighing 32 ounces (960 gm.), and the arch of the aorta was the site of a large aneurysm which had ruptured into the pericardium and caused death. The patient had exhibited symptoms for only 13 hours before death. The pericardial cavity contained a quart of partially clotted blood. Studley states that a large percentage of cases of transposition of the viscera suffer from aneurysm, death generally being sudden. He is inclined to attribute this to the unusual exposure to dilation of the aorta, due to the twist of the arch in this condition. [A.G.E.]

Symbiosis of Influenza Bacilli.—M. Neisser⁴ cultivated colonies of influenza and xerosis bacilli from a case of measles conjunctivitis on blood agar. He continued the cultivation of the mixed bacteria on ordinary agar, and was successful for 20 generations, a condition which had never passed beyond 2 generations before his work. The influenza bacillus would not grow on ordinary agar without the xerosis bacillus; inoculations were made from the fourth and eighth culture. Artificial

symbioses with other influenza varieties were as successful, thus proving that it was not an accidental property of the one colony. When dead xerosis bacilli were used, the cultivation failed, thus proving that it is not the body of the xerosis bacillus, which aids the growth of the other organism, but rather its fermentative action on the medium, which permits this. [E.L.]

The Mortality Due to Congenital Malformation.—The specific problem investigated by R. Pearl¹ is stated by him in the form of the following question: Is there any evidence that, with respect to all abnormalities sufficiently great to cause the death of the individual possessing them, one sex is more variable than the other? The material used consisted of the returns of the mortality due to malformation in the entire United States as reported by the last census. The entire deaths were 1,469 males and 1,226 females. This mortality has been reduced by Pearl to the frequencies per million of the number of males and females alive at each age period. The totals are 1,499 males and 1,283 females per million, showing that malformations included in these data occur more frequently in men than in women. [A.G.E.]

The Occurrence and the Demonstration of Intracellular Toxins.—Allan Macfadyan,² by a modification of Buchner's method of obtaining intracellular proteids, has succeeded in preparing large quantities of bacterial cellular toxins. Buchner extracted the ferment-principle of yeast cells by breaking them up, by triturating them with sand and then filtering under pressure. The filtrate was capable of producing alcoholic fermentation in sugar. In order, however, to procure the most active intracellular substance, it is necessary to cause as rapid disintegration of the fresh cells as possible; and, at the same time, to avoid all heat or other modifying factors. Moreover, the cell juices so obtained must be employed immediately. Macfadyan's method consists in taking fresh bacterial agar cultures and breaking them up in a special apparatus, which is briefly described in the paper. While the trituration is going on, the apparatus is kept in liquid air, which, by freezing the bodies of the bacteria, facilitates their fracture and prevents changes. Very active substances have been obtained from the bodies of typhoid bacilli and also from those of staphylococci and streptococci. By injecting intracellular typhoid toxins into monkeys, there was obtained a serum active not only against typhoid cultures, but also against their intracellular toxins. This serum not only protected animals against both of these, but also had a distinctly curative power. The method will probably be of value in obtaining bacterial toxins in those diseases the bacterial causes of which do not produce extracellular toxins, but produce their effects by means of the poisons contained in the bodies of the microorganisms; such as cholera, typhoid fever and plague. The author has also extracted and tested the juices of blood-corpuscles. Photogenic bacteria lose their property when disintegrated in liquid air. Photogenesis is, therefore, probably a function of the living cell. The disintegration of the infected nervous system completely destroys the rabie virus—an additional evidence of the organized nature of the virus. [D.R.]

Specific Antibodies after Cutaneous Infection.—F. Kasten³ controlled Hoffman's work, who found that cutaneous infection of rabbits with typhoid fever bacilli produced agglutinins in their blood-serum, and that while this agglutinating strength does not develop so well as when the bacteria are injected intravenously, it is as great as on intraperitoneal injection. He worked with typhoid bacilli, staphylococci and cholera organisms. His results with rabbits showed the truth of Hoffman's conclusions. In no case could organisms be cultivated from any of the tissues of the rabbits, thus proving that they are killed in the superficial structures and that the substances produced in the blood-serum are derived from the poisons in the dead bacteria. The same results as above noted were derived by rubbing dead cultures into the skin. The agglutinins were even present in greater number, than where living organisms were used. [E.L.]

Changes in the Medical Corps of the U. S. Army for the week ended March 12, 1904:

STONE, RANDALL C., contract surgeon, now on temporary duty at Fort Hamilton, is relieved from further duty at Fort Screven, and will report at Fort Hamilton for duty.

MAUS, Lieutenant-Colonel LOUIS M., deputy surgeon-general, is granted leave for one month on surgeon's certificate, to take effect upon the arrival of Captain Elmer A. Dean, assistant surgeon, at Fort Riley.

DEAN, Captain ELMER A., assistant surgeon, leave granted February 15 is extended fourteen days.

MOSELEY, Lieutenant-Colonel EDWARD B., deputy surgeon-general, is granted leave for one month from about March 1, with permission to apply for an extension of three months and permission to go beyond sea.

HARVEY, Colonel PHILIP F., assistant surgeon-general, is granted leave for one month, with permission to apply for an extension of one month.

WOODRUFF, Major CHARLES E., surgeon, is relieved from duty at Camp McGrath, Batangas, and will report to the commanding general, First Brigade and post of Manila, for assignment to duty at Santa Mesa Garrison.

MCANDREW, First Lieutenant PATRICK H., assistant surgeon, is granted leave for two months, with permission to apply for an extension of fifteen days.

KULP, Captain JOHN S., assistant surgeon, is relieved from duty as attending surgeon and examiner of recruits at Philadelphia, Pa., to take effect upon the completion of his examination for promotion, and will then proceed to Fort McDowell for duty.

HENDERSON, JOHN L., sergeant first class, Army General Hospital, Washington Barracks, will proceed to Fort Worden, to relieve Sergeant First Class Willis S. Yates. Sergeant First Class Yates will, upon expiration of furlough, report at Vancouver Barracks for duty.

FELTS, ROBERT D., contract surgeon, is granted leave for one month from about March 15, with permission to apply for an extension of one month.

COMBE, JOSEPH K., contract surgeon, will be relieved from duty at Fort Brown and proceed to Fort Sam Houston in time to arrive not later than March 15 for duty.

EDGAR, JR., First Lieutenant BENJ. J., assistant surgeon, having reported to the adjutant general of the Army, will upon the expiration of leave proceed to rejoin his proper station at the United States General Hospital, Presidio.

MARRY, WILLIAM C., contract surgeon, leave granted for ten days is extended eight days.

RAYMOND, THOMAS U., surgeon, will be relieved from duty at Jefferson Barracks upon the arrival of Major Wm. B. Banister, surgeon, at that post, and will then proceed to St. Louis, Mo., for special duty at the Louisiana Purchase Exposition, with a view to exercising supervision over the sanitary conditions on the exposition grounds.

Changes in the Medical Corps of the U. S. Navy for the week ended March 12, 1904:

THOMPSON, E., passed assistant surgeon, detached from the Marine Detachment, Culebra, and ordered to the Des Moines—March 4.

FURLONG, F. M., passed assistant surgeon, detached from Naval Station Guantanamo, and ordered to Marine Detachment, Culebra, W. I.—March 4.

ORVIS, R. T., passed assistant surgeon, detached from Marine Detachment, Culebra, and ordered to Naval Hospital, New York—March 4.

ANGONY, G. L., passed assistant surgeon, detached from Panama Marine Brigade, and ordered to Naval Station, Guantanamo, Cuba—March 4.

RICHARDSON, R. R., assistant surgeon, detached from the Amphitrite, and ordered to Naval Hospital, Pensacola, Fla.—March 4.

STEEP, J., assistant surgeon, detached from the Navy Yard, Boston, Mass., and ordered to the Des Moines, temporarily, and then to Navy Yard, Boston, Mass.—March 4.

SPRATLING, L. W., surgeon, detached from the Bureau of Medicine and Surgery, and ordered to the Marine Battalion, on the Isthmus of Panama.—March 7.

Changes in the Public Health and Marine-Hospital Service for the week ended March 10, 1904:

WEETENBAKER, C. P., surgeon, to report at Washington, D. C., for special temporary duty—March 5, 1904.

WICKES, H. W., passed assistant surgeon, granted leave of absence for one day—March 4, 1904.

VON EKDORF, R. H., passed assistant surgeon, to proceed to Delaware Breakwater quarantine for special temporary duty—March 8, 1904. Relieved from special temporary duty at Delaware Breakwater quarantine, on account of sickness and directed to rejoin his station at the Hygienic Laboratory, Washington, D. C.—March 10, 1904.

BOGGER, J. S., assistant surgeon, Bureau letter of March 2, granting Assistant Surgeon Bogger three days' leave of absence from February 18, 1904, amended so that said leave shall be on account of sickness—March 4, 1904.

SIMONSON, G. T., acting assistant surgeon, granted leave of absence for five days from March 15—March 10, 1904.

STATON, L. W., acting assistant surgeon, granted leave of absence for two days from March 3—March 4, 1904.

Boards Convened.

Board convened to meet at New Orleans, La., March 21, 1904, for the physical examination of officers of the Revenue Cutter Service. Detail for the Board: Surgeon C. P. Wertenbaker, chairman; Passed Assistant Surgeon L. L. Lumsden, recorder.

Board convened to meet at San Francisco, Cal., March 21, 1904, for the physical examination of officers of the Revenue Cutter Service. Detail for the Board: Passed Assistant Surgeon W. G. Stimpson, chairman; Assistant Surgeon Carl Ramus, recorder.

Board convened to meet at the Marine Hospital, Port Townsend, Wash., March 21, 1904, for the physical examination of officers of the Revenue Cutter Service. Detail for the Board: Passed Assistant Surgeon J. H. Oakley, chairman; Passed Assistant Surgeon M. H. Foster, recorder.

Board convened to meet at Washington, D. C., on the call of the chairman, for the physical examination of officers for promotion and applicants for admission into the Revenue Cutter Service. Detail for the Board: Assistant Surgeon-General L. L. Williams, chairman; Assistant Surgeon-General W. J. Pettus, recorder—March 9, 1904.

MARCH 26, 1904.

\$5.00 YEARLY.

The Campaign against Yellow Fever.—Dr. Kober estimates that since 1793 yellow fever has been the cause of not less than 100,000 deaths in our own country and Cuba—41,348 in New Orleans, 10,088 in Philadelphia, and 7,759 in Memphis. Between 1853 and 1900 it caused 35,952 deaths in Havana. The demonstration of the method of conveyance of the germ, by Reed, Carroll, Agramonte, and Lazear, has made it possible to extinguish the disease in the United States and Cuba, but in Central and South America it still prevails. How it can be rooted out of these countries is shown by Dr. Liceago, President of the Board of Health of Mexico. The facts as to the transmission of the disease by *Stegomyia fasciata* are clear; not so the mechanism of prevention. Dr. Liceago sets these forth as: 1. Isolation of suspects to prevent them from being stung by mosquitos, until they are incapable of infecting the mosquito. 2. Destruction of the infected mosquitos, preferably by means of sulfurous acid. 3. Extermination of the uninfected mosquitos in their native habitat. Stringent execution of the precautions necessary to carry out these possible measures will speedily end the reign of yellow fever in the world. Once absolutely rid of the vicious circle, the disease can never be reproduced anew, and the growth of civilization can be effected in these tropical and semi-tropical countries hindered up to now almost solely by reason of the transmission by the mosquito of the germs of malaria and yellow fever. The article of Dr. Liceago is published in a late number of *Public Health Reports*, and should be read by all who are practically interested in the abolition of the disease. He enters into all the details of the methods of procedure.

"The Pollution of Deep Wells" was the subject of a paper before a scientific society, in which was described an interesting experiment conducted by the United States Geological Survey and the Geological Survey of Georgia, acting in cooperation, to determine the liability of contamination of the deep wells and springs in the vicinity of Quitman, Georgia, by the proposed action of that city in turning the public sewage into an underground stream through a bore hole. To test the matter, the surveys mentioned inserted two tons of salt into the well into which it was proposed to turn the sewage. Samples of water were taken before the experiment to determine the normal chlorin of the

waters, and at short intervals during and for some time after the experiment. The report concludes that, "on analyzing the samples it was shown that the salt had entered all of the deep wells in town, thereby demonstrating that the insertion of sewage would have contaminated all of the wells, and possibly led to a dangerous epidemic." Undoubtedly the water of wells is often polluted by drainage, and the experiment verifies the danger, which should help health officers in their work. One wonders, however, if there is not a slight fallacy in the conclusion introduced by the doubt if microorganisms might not be prevented from passing by the earth filtration, while a solution of salt would be able to permeate the medium. Why not use pathogenic bacilli themselves for a more convincing test?

The campaign against noise promises to become more active than ever during the coming summer, and it is the duty of every physician to aid in it, and of every health board to wage it actively. The wide publication of the morbid results of our morbid method of conducting our Fourth of July celebration, the harvest of death by accidents and tetanus, should help every administrative officer to demand a rigid execution of the law against the deadly toy pistol and every similar noise-making instrument. In New York the Health Commissioner suggests the appointment of a special Cat Inspector, to lessen the nightly eloquence of these sleep-destroyers. But far more important than such measures are those directed against useless street noises which make the well sick, and the sick still more so, from the continuous battering of the ears and nervous system with jars that create a state of overtension and hyperesthesia. Chief among these at present are the trolley cars, which shake the ground and rush through our streets like huge engines of reckless evil, with banging bell and roar. The cars should be run slower, at least during the late hours of night. The keeping of cocks and chickens should be forbidden in cities, and street hawkers, newsboys, etc., compelled to stop their bellowings, and ringings, and screechings. The playing of pianos, and especially mechanical musical instruments, talking machines, etc., must be at least restricted to the day and evening hours.

College Courses Suited to the Needs of Prospective Students of Medicine.—A large proportion

of our profession has appreciated the value of a liberal education for physicians, even though they themselves may have been debarred its advantages. The extra time sacrificed in obtaining a preliminary degree has kept many students from taking an academic course before beginning medical studies and the need of preparing men to enter professional work earlier than was usual with college graduates a few years ago has been recognized by a large number of our more progressive colleges and universities. President Eliot believes that the secondary schools are at fault in not advancing their students as rapidly as they should. The German or French student is ready to enter the university at a much earlier age and with an equally good, if not better, preparatory education, and this is not because he is a brighter boy than an American boy, but because their secondary schools are much more effectual. If our boys were all prepared to enter college at 16 or 17, as is perfectly possible, they might have the liberalizing influence of a college course and the best medical courses offered in this country and still enter the profession at 23 or 24 years of age. But until improvements can be made in the fitting schools, colleges must make an effort to adapt themselves to the needs of the times. Various plans have been devised so that men may enter their professions earlier and still not entirely sacrifice their liberal education. At Harvard the student is allowed to complete the work for the bachelor's degree in three years instead of four as formerly, and in President Eliot's latest report we notice the statement that, "At the present rate of increase in the number of three-year men it will not be long before the majority of each entering class will obtain the degree in three years." At Cornell, Columbia, Michigan, Bowdoin, and a number of other colleges, courses are arranged especially adapted for preparation for medicine, and the student is allowed to enter the professional school at the end of three years, receiving his arts degree after the first year of medical study, thus obtaining the arts and medical degrees in seven years. A number of colleges, such as Brown, Williams, and Princeton, give courses preparatory for medicine, and graduates of these special preparatory courses are accepted as second year students by a number of reputable medical schools. One of the best plans of which we have knowledge is that which has been adopted by Wabash College recently.¹ "The following optional course of study is given students who propose entering professional schools: A four years' course of study, of which three years shall be prescribed work, all electives being reserved for the fourth year. Students taking this option will be permitted, if they so desire, to pursue their fourth year in attendance at a professional school approved by the trustees of the college; retaining in the meantime their college standing and responsibility and being eligible to graduation with their class on presentation of proper credit earned in this way." It seems to us that this will prove the most desirable arrangement for many students. The student gets a satisfactory liberal education and the liberal arts college recognizes the educational value of his professional train-

ing and gives him substantial credit for it. A difference of one year's time will be the deciding factor with many students for or against a preliminary academic education. This will prove a much more satisfactory arrangement to the medical faculties than that of receiving as second year students men who have taken an equivalent of the first year's medical studies in their arts course. Without credit is allowed, the student simply covers the same ground twice, an unnecessary waste of time, and studies like medical chemistry, physiology, etc., can be taken more satisfactorily in some respects at the medical schools than at college. If other colleges of our country will follow the example set by Wabash they will hold a considerable number of students who would prefer to take their arts course in such a college rather than in a large university, but who at present choose some one of the larger universities that have adopted the plan of giving a year's credit toward the art degree for work done in their professional schools. The efforts on the part of colleges and universities throughout the land to adapt their courses to students who expect to pursue professional studies is encouraging, for it shows that our educators are trying to understand the needs of classes of men having widely differing aims. It has seemed a mistake that some so-called liberal arts colleges have so long held to the idea that all men should have their minds shaped in the same mould quite regardless of what their career in life was likely to be. The institutions which have taken the lead in needed educational reforms have not been, and will not be the losers, either in the number and quality of their students or in reputation.

The Hygienic Significance of Marriage.—Nature has invested the gratification of sexual desire with a sensation of pleasure, thus stimulating the individual to perform his procreative duty and contributing to the reproduction and preservation of his species. An unrestrained and thoughtless pursuance of this gratification will lead to baneful results both to the progenitors as well as to the progeny. Ever since the existence of the species *homo sapiens*, the expediency of regulating sexual intercourse has been recognized and methods thereto pertaining, devised and attempted with greater or less success. There can be no doubt that a regulated intercourse, conforming with the laws of nature, is an indispensable mainstay for the lasting physical and spiritual existence and the welfare of a nation. Under our prevailing social conditions, marriage is an institution highly conducive to the health of both husband and wife. Statistics prove that among married men over 20 years of age, and women over 40, the mortality rate is far less than among those who remain single. Among the widowed and divorced the mortality is exceptionally great. Suicides among the unmarried are much more numerous than among the married. The matrimonial state promotes temperance in every form. To the well-regulated and settled mode of living of the married, their limited exposure to venereal infection and their relatively infrequent abuse of alcohol, their greater longevity may be ascribed. Furthermore, the probable duration of life of a married man of 30 exceeds that of his unmarried brother by five years, and the wife, in

¹ Journal of the American Medical Association, March 5, 1904, p. 668.

spite of the dangers of pregnancy and childbirth, may expect to live one year longer than a single woman of the same age. The beneficial results of marriage upon the participants become still more apparent when contemplating the effect upon the offspring. The fruit of marital intercourse is better protected and better able to withstand the dangers of parturition than that illegitimately conceived. Furthermore, legitimate children may expect a more rational and more careful nursing during the crucial period—their first year of life. All statistics agree on this point and it is noteworthy that in Europe 448 children out of 1,000 born in wedlock were stillborn, while 653 were stillborn of those illegitimately begotten. The mortality is also far greater among illegitimate children. Upon studying the causes of their deaths we find that it is very frequently attributable to diseases of digestion, probably due to the fact that such children are rarely nursed at the breast of the mother, and less attention is given to their artificial feeding.

The Detrimental Effects of Marriage.—Marriage between immature individuals is especially injurious to both the male and the female, and in many instances leads to an untimely decease of the one or the other. The same applies to alliances of persons well advanced in years. Men advanced in years have succumbed to the exigencies of the early married state when their cardiac action and blood circulation were no longer strong enough to respond to the abnormal demand. Miscarriages among women who enter wedlock prematurely are of such frequent occurrence that it would be expedient to formulate laws prohibiting ministers and the authorities to sanction wedlock between the insufficiently matured. Cannot the misery of the mother and the subsequent unhappiness of the family often be directly traced to the premature marriage of parents? How often the children evince in their breeding the undeveloped and immature physical and mental state of the parents! How often are they the victims of inexperience and ignorance! Children born of too youthful parents are likely to be feeble, and idiocy and malformation are more common among them than among those born of mature progenitors. Likewise parents in advanced age, mother over 40, father over 50, usually give birth to infirm children. Very young women and those approaching the climacteric are more prone to bring forth twins. Conditions which enfeeble and weaken the organism of the parents naturally affect the offspring similarly—it would seem that the ovum of a weakly mother possesses less vitality or that the embryo is insufficiently nourished. The female system suffers when the intervals between the periods of gestation are too brief. According to data, the third and the fourth child is the most robust, and a decrease of strength is apparent in the fifth. Pregnancy should not occur more than once every two and a half years, for only then the mother is able to nurse the child sufficiently long. The economic circumstances play an important part in the physical condition of the issue. The problem of supporting and caring properly for children becomes more difficult as they increase in age and number. No more children should be begotten than can, in all likelihood, be adequately maintained. The

pernicious effects of alcoholic intemperance in the parents manifest themselves in their children. These show a lack of vigor, retarded development, and a low degree of resistance, and above all, hypersensitiveness and asthenia of the nervous system.

The Selection of the Spouse.—The fact that the offspring may be the heir to the morbid tendencies of the parents, makes it imperative that the greatest care should be exercised in the selection of a spouse, but one should not grow too wary and hypercritical. No generation ever existed which did not possess some abnormality, and a rational mode of life will tend to ameliorate certain untoward affections. The rule of the life insurance companies to inquire into the family history of the applicant would be a prudent course for those intending marriage to adopt. Even if the aspirant to marriage evinces no unhealthy symptoms, a minute study of the physical condition of his immediate relatives might disclose the morbid tendency to which he or she is heir. Whenever anomalies and signs of degeneration repeatedly present themselves in preceding and present generations, thus proving the ascendancy of such morbid affections, we may assume that subsequent generations will not be spared, and marital union with a member of such a family should be emphatically interdicted. Among the lower classes, and for that matter also among those of higher standing, the fact that "there is tuberculosis (or insanity) in the family" is perhaps the only deterrent to contemplated conjugal union, and here it is the graphic and obvious manifestation of the diseases which inspire the dread. Of the nature of the numerous other grave and disastrous affections the public in general is woefully ignorant. Unless the dangers that await them are imparted to them in an intelligible manner there can be little hope for the amelioration of present conditions.

Crime in lying-in homes is becoming more and more evident in the fact of the increase of the number of such institutions, in the brazen methods pursued in advertising them, and in the insinuated temptations and offers made in letters and circulars. The unblushing openness of the statements as to a "division of the spoils," or fees, shows that these fellows are really, though perhaps not legally, outside the pale of the profession, and that every physician should treat them as they in fact are—abortionists and participating criminals. From a circular letter addressed to one of our subscribers by the proprietor of one of these institutions, we quote:

For such cases as demand immediate interference in the early period of pregnancy, whenever in your own and my opinion such steps are indicated, the minimum fee of \$35 does not apply to those who can well afford to pay a fee more in keeping with the requirements of the case. The physician sending such a patient must of necessity give up a considerable portion of his time to the interests of the case, and in recognition of his services and assistance, I make it a rule to remit to him 20% of the gross fees received from the patient.

Blackmail and crime is seen in every hint and sentence of this nauseating literature, and the profession is naturally charged by the lay public with instigating or profiting by the breaking of the law. A few prosecutions carried out by the attorneys of medical societies

would exonerate us, and at least make the nefarious business harder to carry on with profit and success.

Preparations for getting the children into the country are now seasonable, and the large number of organizations devoted to this hygienic purpose deserve the help of the charitable, whether professional or lay. Such institutions as the Children's Seaside Home of Atlantic City, the Sanitarium Association of Philadelphia, and the like, in all our large cities, should be imitated by similar organizations in smaller cities, for in them the children's health often suffers as much from confinement, bad ventilation, and insanitary conditions, as in the slums of the great centers. Last summer was an exceptionally cool one and the use of the out-of-town resorts by children, their mothers and caretakers, was less than usual, but with a probably exceptionally hot summer before us, there would be a great increase of children's diseases, should the little ones not have easy means of reaching the coolness, fresh air, sunshine and bathing of the associations designed to give them outings. The Philadelphia Sanitarium Association has steamers which run daily to and from Red Bank. The number of trips made last year was 946, the total number of admissions being 96,541, the number of bathers 24,958. The economic aspect is shown in the fact that the total annual expenses of its beneficent work amounted only to about \$12,000 or \$13,000.

The Milk-supply of Cities.—At a recent symposium on the character of milk supplied to cities, held under the auspices of the Medical Society of the County of Albany, N. Y., the production of sanitary milk from the standpoint of the producer was discussed by R. A. Pearson, of Cornell University. Lack of consideration of the producer he finds to be one of the causes of the slow advance in the movement for better market milk. Laws are passed to regulate producers; they would welcome such extension of the laws and would prevent dishonest competition by certain of their number who make unwarranted claims regarding the quality of milk offered for sale. Dairy men would also endorse the enactment of regulations regarding the care of milk bottles when in possession of the customer. These are important points, but to our mind a more cogent factor was touched upon in the statement that there is a lack of general public complaint about the character of our market milk. "All milk looks alike and tastes alike to most people, whether it was produced under sanitary or unsanitary conditions, and those matters are not considered." A remarkable feature is the position of institutions, especially hospitals, that buy milk on contract. As a rule they make no stipulation as to sanitary quality. Dairy men naturally think that milk good enough for institutions caring for the sick must be perfectly satisfactory to well people. Why furnish better? A shameful proof of these assertions was recently given by the State Veterinarian of Pennsylvania, who found by inquiry that only three of the hospitals in Philadelphia paid any attention to the purity of the milk they fed their patients. The only determining question with the others was that of price. Fortunately this

deplorable state of affairs has been changed. People get what they demand—and pay for. In the discussion referred to, Dr. Charles Harrington said that because people want early morning delivery of milk, with the cream at the top, milkmen supply them with milk bottled the previous day. If milkmen should suggest bringing the milk in their large receiving cans at ten o'clock on the morning of its receipt, and measuring it into the consumer's pitcher, they would soon lose their family trade. There are two sides to the pure milk question; laws against the producer should be made and enforced with a full appreciation of the position of the consumer.

Quack Nursing Schools.—The trained nurses of the country should hasten to effect their organizations, for it is only through union and corporate power that they and their allies, the medical profession, can secure laws to protect them and the public from quack nursing schools. The astute owners of the schools are financially cunning. The numbers of such institutions are indeed multiplying rapidly, and are pouring out their "graduates" as numerous as possible while yet an unaroused public sentiment may permit. The president of one of these schools is sending out appeals to physicians which show a curious mixture of characteristics. Here is one written upon the official paper¹ of the President's "school," and addressed to himself:

HON. _____

Dear Sir:—I am in sympathy with extending information regarding the nursing of the sick as widely as possible. You are permitted to refer to me in the matter as occasion may arise. It being understood that this permission does not carry with it any financial responsibility. Very truly yours,

To this strabismic letter our correspondent answered:

HON. _____

March 17, 1904.

Dear Sir:—Your letter inviting my signature to the blank form recommending directly the more general dissemination of knowledge of nursing, and indirectly the Philadelphia School for Nurses, is received. The first thought receives my unqualified commendation and support. The second, the Philadelphia School for Nurses, in its present aims and claims, a decidedly qualified support. We can heartily commend this school to wives, sisters, and mothers who desire to minister more intelligently to the needs of the sick ones in their homes, that is, we recommend it to persons who do not intend to make a profession of the art of nursing.

On pages 21 and 27 of the report of your school we note that you distinctly propose that your graduates shall enter the professional field, and shall pose on terms of equality with the women who have worked and studied the practical and scientific art of nursing for two or more years in some well-appointed hospital. A sick person looking for a nurse is not supposed to be acquainted with the kind of equipment possessed by the candidate for the place. He can be deluded by thinking that a trained nurse should naturally mean one thoroughly trained in practical nursing. We are constrained to say we believe your school in this respect is enacting what should be made a criminal role. You are an eminent jurist, and I would humbly ask whether in all fairness there should not be some well-understood public distinction made between a course of ten weeks in theoretic (possibly a semblance of practical) nursing, and one of two or more years painstaking effort in a hospital? Has not sick humanity a right to be protected from such imposition? Wishing the institution all success in its proper sphere, I am

Respectfully yours, H. C. MASLAND.

¹ With a pompous and awe-inspiring array of D.D.'s, Hon.'s, Presidents, Reverends, and one M.D., all "representing the American National Red Cross, etc., Clara Barton, National President."

AMERICAN NEWS AND NOTES.

GENERAL.

Miscellaneous.—Drs. E. Marchoux and P. L. Simond, of the Paris Pasteur Institute, arrived in Rio Janeiro, February 17, to study yellow fever. A fund has also been raised by the merchants and wharf owners of Hamburg to send Drs. Otto and Neumann, of the Institute for Tropical Diseases, to South America to study these diseases on the spot.

Requests to Charity.—Baltimore: By the will of the late John Mohn, \$16,000 is left to a number of charitable institutions, St. Vincent's Male Orphan Asylum receiving the largest sum, being \$5,000.—Philadelphia: By the will of the late Mary P. Wernwag, \$60,000 is left to 2 sons, and upon their death to the Home of the Merciful Saviour for Crippled Children.

Germs in Filthy Money.—Representative Gaines, of Tennessee, who is pushing his bill to compel the use of clean money, asked Dr. Darlington, the Health Commissioner of New York, to make an examination of different kinds of money to ascertain to what extent disease can be transmitted by them. Dr. Darlington has made the examination requested, and has sent a report, in which he says: "Coins, glass and paper were used for the purpose of determining whether germs would live upon them any length of time. Upon the coin, copper, nickel and silver, diphtheria bacilli all died within 48 hours, while upon the glass and paper they were still alive, which proves that the metal had distinct antiseptic properties, while paper did not, so that bills would probably carry disease, while coins would only do so within a short period of time. So far as paper money is concerned, it has no deleterious effect upon pathogenic bacteria. Dirty bills taken at random from stores show enormous numbers of bacteria upon them. Thus from the washings of one bill were obtained 135,000 bacteria, from another 126,000. Comparatively clean bills gave 2,250 and 2,000 respectively. Upon all of these staphylococci were found. Experiments in actually producing disease from these bills are not yet concluded, but it has been sufficiently demonstrated that money may carry disease."

Progress in Science as Related to Crime.—How the progress of scientific discovery may influence the rendering of justice has been shown in a striking way by the recent decision of the Judicial Committee of Revision of Trials in the case of the Parisian chemist Danval. The latter was found guilty 25 years ago of the murder of his wife by having poisoned her with arsenic, and was sentenced to transportation for life. Scientific evidence having since come to light tending to show that he was innocent of the crime, he was granted a free pardon 18 months ago. The Committee of Revision has now unanimously recommended that his application for a new trial, whereby to clear himself finally of the charge, be granted. The remarkable fact of the case is that the evidence on which Danval was found guilty was purely scientific, and that his application has been allowed solely on account of the fact that later scientific investigation has proved the evidence in question to have been erroneous. At the trial, 25 years ago, all the expert witnesses swore that the quantity of arsenic, 1 mg., found in the corpse of Danval's wife, at the postmortem, could not possibly have existed in the system under natural circumstances, and that it was scientifically proved that the presence of such an amount of the poison was incompatible with life. The inference drawn was, of course, that the arsenic had been administered by Danval, and it was largely on this evidence that he was found guilty, with, however, extenuating circumstances. Since the trial the researches of various doctors and physicists, including MM. Armand Gautier, Béhal, and Gabriel Bertrand, have, on the contrary, conclusively demonstrated that the quantity of arsenic mentioned can and frequently does exist in the human body in a normal state. Presumption is thus set up in favor of Danval's defense, which was that the presence of arsenic in his wife's remains was explained by her having been in the habit of taking certain medicines. The decision of the Committee of Revision has been entirely grounded on the recent scientific conclusions above mentioned.—[Paris Correspondence, *London Telegraph*.]

NEW YORK.

Typhoid at Poughkeepsie.—Information March 15 says: Within a few weeks many cases of typhoid fever have developed in this city, and new cases are being reported daily.

Year's Mortality in New York.—A report just issued by the Health Department shows that of 67,864 deaths that occurred here last year, 9,714 were due to pneumonia. The excellent results attained here by proper vaccinations are demonstrated by the fact that during the entire year there were but 43 smallpox cases reported, from which but 5 deaths resulted. During the year there were 31,174 marriages recorded, and 94,755 births.

Health Certificate before Marriage.—A bill has been introduced in the New York Assembly providing that all persons must obtain a physician's certificate before a marriage license can be issued to them. The bill is designed to make

greater restrictions against the marriage of imbecile and half-witted persons, and also to prevent those having tuberculosis and other diseases from marrying.

Measles in New York.—An epidemic of measles and scarlet fever has broken out in the Bronx, and at the present time there are more than 400 cases of measles on record with the Bronx Board of Health, and between 150 and 200 cases of scarlet fever, with a daily increase of cases. The Department of Health in the Bronx is crippled by the need of disinfectors, there being only 4 men to do this work. It is expected that additional funds will be provided soon.

Regard Pneumonia as Infectious.—The Rochester Health Bureau has decided to treat pneumonia as an infectious disease, and to ask physicians to report all cases just as they report diphtheria and smallpox. A new map is to be placed in the Health office, upon which is to be designated all cases of pneumonia and the sanitary conditions accompanying them. Because the cases have not been reported it is not known how many there have been in Rochester this winter, but it is known that pneumonia has been more than usually prevalent.

Ophthalmic Disease in New York.—Trachoma and other eye diseases have again appeared to such an alarming extent that Health Commissioner Darlington has asked the Board of Estimate for an appropriation of \$30,000 for the immediate establishment in one of the hospitals of several wards devoted exclusively to these diseases, the employment of a staff of oculists, special nurses, orderlies and attendants. The Board at once authorized the expenditure. The Health Department is also planning a special hospital on the lower East Side for the treatment of trachoma.

Big Increase in Deathrate.—According to the weekly reports of the Department of Health the severe winter has added alarmingly to the deathrate through the many fatal cases of pulmonary troubles and the diseases contributing to them. The total deaths for the week ending at noon March 14, 1903, were 1,416, the deathrate being 19.79. The report for this year for the week, up to noon, March 12, showed 1,779 deaths, the rate being 24.18. On March 14, 1903, the week's total of cases of tuberculosis pulmonalis was 279. Last week there were 455. Cases of measles, most largely contributing to pneumonia, were 290 for the corresponding week last year and 1,579 this year. In addition to this, scarlet fever is very prevalent, the report for last week being 496, as compared with 319 last year.

Mt. Sinai's New Hospital, which occupies an entire block, was dedicated on March 16, an appropriate address being made by Governor Odell. The hospital cost \$2,500,000 and is arranged on the pavilion plan, except that the 10 buildings are connected by their ground floor corridors. Five of these, the medical, surgical and private hospitals, the children's and the isolating pavilions, are for the housing of patients and contain 456 beds. On the roof of each of these buildings is a glass inclosed solarium for convalescent patients. In the remaining buildings, the central, or administration building, the kitchen and laundry, the pathologic building, the dispensary and the nurses' training school, reasonable provision has been made for the standing needs of progressive medical science and hospital administration.

Low Smallpox Record in New York.—According to copies of Greater New York's deathrate and contagious cases report for 1903, the number of cases of smallpox in New York last year was only 45 and the deaths therefrom 5. There has scarcely been a week in Philadelphia in the last 6 months that the cases and deaths of the dread disease did not exceed the figures of New York for the entire year. The officials ascribe New York's freedom from the disease to be due to a compulsory vaccination law which prevails in that city. It is explained that the vast population of Greater New York is vaccinated, and that the disease cannot secure a foothold. The fact that employers of labor will not employ unvaccinated persons in New York has contributed largely to the success of the vaccination crusade there.

Effects of Open-Air Treatment.—Figures bearing upon the permanency of the good results obtained by the open-air and rest treatment of tuberculosis are contained in the 19th annual report of the Adirondack Cottage Sanitarium, which has just been issued. Of 1,500 patients who have been discharged from the institution from 2 to 17 years, 434 could not be traced, leaving 1,066 which have been traced. Of these 46.7% are still living; 31% are known to be well at present; in 6.5% the disease is still arrested; 4% have relapsed; 5.2% are chronic invalids, and 53.3% are dead. Thus it has been found that 31% of all those discharged from 2 to 17 years ago have remained well. During the last year 296 patients were treated, which is the largest number treated during any year since the sanitarium was established. Of these 298 there remained in the sanitarium at the time the figures were completed 106, leaving 192 to be reported on for the year. Fifty-two of these, or 27%, were discharged apparently cured. Eighty-nine out of the 192, or 46%, were discharged with the disease arrested, and 32, or 17%,

were discharged as improved; 14, or 7%, were discharged as unimproved or failed; 1 case was recorded as doubtful, and 4 patients, or 2%, died.

Prevention of Tuberculosis in New York.—The Committee on the Prevention of Tuberculosis of the New York Charity Organization Society is going about its work of education with a thoroughness and an intelligence which should be a guide and stimulus to every organization which is engaged in the campaign against the great scourge. Its effort to enlist the interest and cooperation of the labor organizations in this work is highly commendable and is practical. If the latter bodies, particularly those comprised in the United Garment Workers of America, take hold of the work in earnest they can accomplish far-reaching results. Nothing they could do to better the conditions of the wage earners would be so beneficial to themselves and to the world at large as would efficient aid in stamping out conditions under which tuberculosis develops and thrives.

Cat and Dog Law.—The New York city authorities have decided to push a dog and cat bill in the Legislature similar to the law now in existence in cities of the second class. The act requires the licensing of all dogs in the city, the owners to pay a license fee of \$2 on May 1 of each year. Each dog must wear a collar on which will be fastened a metal tag showing that the dog is licensed, and any dog running at large without such a tag shall be seized and impounded. The owner will have an opportunity to secure possession of the dog upon the payment of \$2, but if the animal is not claimed it may be disposed of to some other person who will pay the license fee, or it may be destroyed. Cats are to wear a collar upon which will be inscribed the name and address of the owner. If a cat is found without such a collar it will be impounded with the same provisions for its recovery as for dogs. The Mayor, if he deems it necessary for the protection of the public health of the city, shall have power to prohibit dogs from running at large, whether licensed or not, unless they are securely muzzled or led so as to prevent them from biting. All dogs running at large in violation of such an order may be seized the same as if they were not licensed. The enforcement of the proposed new ordinance is placed with the Health Board.—[N. Y. Sun.]

PHILADELPHIA, PENNSYLVANIA, ETC.

Chester to Fight Tuberculosis.—The Board of Health has planned a campaign against tuberculosis in this city and physicians who are treating the disease have been asked to report all cases, so that the houses can be fumigated and better protection offered the community.

Philadelphia Physicians Fined.—Three physicians of Philadelphia have been fined on the ground that they had violated the Act of Assembly of June, 1895, which prohibits the sending of persons having contagious diseases to hospitals and other places in public conveyances and requiring physicians to report such cases to the Board of Health.

Polluted Water and Typhoid in Philadelphia.—The health authorities are not now fully satisfied that the epidemic of typhoid fever in this city is due entirely to polluted water. They suspect that defective drainage systems may be responsible, to some extent, for the outbreak. Accordingly, they are considering the advisability of conducting a house-to-house canvass to inspect the drainage facilities.

Filtered Water for Public Schools.—The Board of Education has decided to ask Councils for a special appropriation of \$2,000 to repair and maintain 42 large filters which are now out of commission. All together there are 100 filters installed in school buildings throughout the city, furnishing pure water in emergency to residents in the neighborhood of the schools. The bill for the special appropriation will be introduced at the reorganization of Councils, April 4.

Medical Students Petition the State Board of Medical Examiners.—The upper classes in the University Medical School have presented a petition to the State Board of Medical Examiners to change the recent ruling by which they refused to accept the New York examinations for admittance to practise in Pennsylvania. The ruling causes considerable trouble, and in the petition it will be asked that the New York examinations be accepted in part, and the only examinations required be those in subjects which are not covered in New York.

The Henry Phipps Institute.—A cable from Professor Maragliano announces his illness and inability to give his lecture under the auspices of the Phipps Institute scheduled for March 25. It has, therefore, been indefinitely postponed. The institute will entertain at dinner on the 28th the delegates who have been called to meet in Philadelphia to consider the question of a national league against tuberculosis, and the holding of an American Congress against tuberculosis. Dr. L. F. Flick will give a luncheon to the delegates on the same day just before the meeting, which has been called for 3.30 o'clock. At this meeting, an abstract from Professor Maragliano's paper will be read.

New Sewage Plan in Municipal Hospital for Philadelphia.—A plan for making harmless the wastes from the new Municipal Hospital now in course of erection, devised by John S. Bross, is believed to contain the germ of success which thus far has eluded hospital managements throughout the country. The details have not yet been made public. Every effort is being made to have the new Municipal Hospital completed so that the old hospital buildings may be destroyed by fire. Advertisements have been made for bids for the erection of the light, heat and power plant for the new institution. The small-pox pavilion is entirely completed, but cannot be used until the power plant is installed.

Smallpox and the Unvaccinated.—In a recent address made by Dr. Jay F. Schamberg, he is quoted with making the following statement: Even in communities in which the majority of the people are vaccinated smallpox still causes a considerable mortality among the unprotected. In this city from 1901 to 1903 inclusive 665 persons died of smallpox. The statement may grieve afflicted families, but it is nevertheless the truth that every one of these lives could have been spared. There is no excuse at the present day for any one to perish from smallpox. The man who refuses to have his children vaccinated is guilty of criminal negligence; more so, indeed, that he who stores in his home dangerous explosives.

Typhoid, Pneumonia, and Smallpox.—Pneumonia and other diseases of the lungs helped swell the deathrate last week, and the officials of the Health Bureau look for no amelioration during March, at least. Pneumonia heads the list of the causes of death for the week, claiming 113 victims. Ever since December last, when the disease became prevalent, it has caused more deaths each week than tuberculosis, which, on account of its ravages, was called "the white plague." Tuberculosis last week caused 79 deaths. The fact that 141 new cases of typhoid fever were reported to the Health authorities last week, a decrease of 1, as compared with the previous week, leads the authorities to think that defective house drainage may be responsible for the outbreak. The deaths from typhoid last week numbered 21, a decrease of 4 from those of the previous week. Smallpox is decreasing, and with the advent of mild weather the authorities hope to have the disease stamped out. The new cases last week numbered 30, a decrease of 18 from those of the previous week.

SOUTHERN STATES.

United States Naval Medical School.—The closing exercises of the second session of the United States Naval Medical School were held in the lecture room of the National Museum, on Monday morning, March 21.

WESTERN STATES.

Fight Against Tuberculosis.—The National Anti-Tuberculosis Association has been incorporated in Springfield, Illinois. The object of the organization is to prevent tuberculosis by legislation and through a campaign of education. According to the incorporators, the Association is purely philanthropic. The association is preparing a list of the physicians and business men back of this movement, and instructive pamphlets will be issued. A subscription will be taken, and a free clinic for the treatment of the poor established.

Iroquois Hospital Proposed in Chicago.—The proposal of the Iroquois Memorial Association to establish an emergency hospital in the business district in memory of the victims of the theater fire was indorsed recently at a meeting of the Chicago Medical Society. The action of the society was embodied in a resolution as follows: "Resolved, That the Chicago Medical Society approves the action of the trustees of the Iroquois Memorial Emergency Hospital in their generous effort to give to the people of Chicago a modern, fully equipped, and endowed hospital capable of rendering prompt assistance to those cases of unexpected injury and sickness, which are of daily occurrence, and be it further Resolved, That we, as a society, tender to the hospital our counsel, advice, and professional services whenever required."

Measles among Indians.—There is an epidemic of measles in Indian Territory. This is not a serious matter so far as the whites are concerned, but it is different with the Indians. The measles, especially at this season, is a terror to them, and many deaths result among the fullbloods. Years ago smallpox was their scourge, but of recent years the constant use of vaccine has reduced deaths from this cause to a minimum. There was a time when smallpox in the prison of Indian Territory was a matter of greatest dread. It is not so now. There is scarcely a jail in the territory which does not have smallpox cases during the winter, but deaths are rare. Measles are more dreaded by the prison authorities. At this time there are measles in the Muskogee prison, and also at the Fort Smith prison. At a trial at Muskogee, Central District, a jury became afflicted with measles during a murder trial, and the trial was broken up. At Sapulpa, Western District, a prisoner broke out with measles, and the entire court was exposed. Some of the officials are

now ill of the disease. The same malady prevails in several towns in the territory, and in several instances schools have had to be closed on that account.—[*Kansas City Journal*.]

Chicago's Drinking Water.—The Bulletin of Chicago's Health Department for the week ended March 5, says: Forecasts from the Laboratory: The city water is still bad, all stations—with only one or two exceptions—showing the presence of contamination every day during the week. This condition and the increasing proportion of positive reactions in the Widal test for the typhoid bacillus—about 6% more than the previous week—foreshadow an increase of typhoid fever, which will, of course, be chiefly among those who have been drinking the contaminated hydrant water. All drinking water at the present time should be sterilized by boiling. Cultures show the diphtheria bacillus in about the same proportion as last week. Influenza is still present to a large extent, but the virulence of the germ is somewhat milder. There is a marked increase of staphylococcus present, the germ that causes tonsillitis. During January and February, 180 physicians sent to the laboratory, 487 throat cultures to be examined for diphtheria, influenza, etc., and 575 specimens of blood, sent in by 283 physicians, have also been examined by the Widal test of typhoid; about 25% of these were positive. The positive reactions declined from 35% during the first week of January to 13% during the last week of February, but are again increasing.

FOREIGN NEWS AND NOTES

GENERAL.

An Expensive Hospital with One Patient.—According to the *Daily Mail* of London, the special hospital for the treatment of ringworm, which the Metropolitan Asylums Board built at a cost of £200,000, remained empty until a few days ago, when the record was broken by the admission of a child from Mile End road.

OBITUARIES.

William Frederick Holcombe, at his home in New York City, March 17, aged 77; a graduate of the Albany Medical School. He had also taken special courses in Paris and Berlin. In 1861 he was appointed lecturer on diseases of the eye at the New York University Medical College; later he was professor of eye and ear diseases in the same college; also in the New York Ophthalmic College and Hospital and in the New York Medical College for Women. He was a member of the medical societies of New York, The American Medical Association and the International Medical Society.

Moreau Morris, at his home in New York, March 17, aged 79; a graduate of the College of Physicians in 1848. In 1866 he was appointed health commissioner and later served as superintendent of the New York City Health Department. In 1871 he became surgeon of the Seventh Regiment, N. G., N. Y., and later was appointed tenement commissioner. He was a member of the American Public Health Association, of the Alumni Association of the College of Physicians and Surgeons, and of the Academy of Medicine.

William H. Hawkes, at his home in Washington, March 15, aged 55; a graduate of the University of Pennsylvania, and at one time assistant army surgeon. He had practised in the District of Columbia since 1882. He was a member of the American Medical Association, and at the time of his death was on the staff of the Emergency Hospital and was formerly a member of the faculty of Georgetown University.

D. P. January, at his home in Crowley, La., March 17, aged 66; a graduate of Tulane University in 1860. At the outbreak of the Civil war he was appointed surgeon in the Confederate army and served with distinction throughout the various regiments during the entire war. He was at one time mayor of Crowley and was a wellknown physician in Louisiana.

W. J. McDermott, at his home in New York, March 12, aged 73; a graduate of New York University in 1853. One time member of the New York Assembly. He was a noted surgeon during the Civil war and a personal friend of President Lincoln and General Grant. He was captured and was confined for a time in Libby prison.

Ralph Schuyler Goodwin, at his home in Thomaston, Conn., March 5, from Bright's disease, aged 64; a graduate of the College of Physicians and Surgeons, New York, in 1868; a member of the American Academy of Medicine and of the American Public Health Association, and health officer of Thomaston.

Peter G. de Saussure, from pneumonia, at Riverside Infirmary, Charleston, S. C., March 8, aged 46; a graduate of the Medical College of the State of South Carolina; a member of the American Medical Association and professor of obstetrics, gynecology and diseases of children in his alma mater.

Phillip H. Brothers, from heart disease, at his home in Zula, Ala. March 4, aged 74; a graduate of Jacksonville Medical College in 1853; a

member of the American Medical Association and one time member of the State Legislature of Alabama.

Douglas J. Cameron, at his home in New York, March 14, aged 31; a graduate of Yale University and of the University of Edinburgh. He confined his practice chiefly to the poor and was known on the East Side as the "Good Samaritan."

B. F. Taylor, at his home in New Orleans, March 18, aged 80; a graduate of the Missouri Medical College in 1848. For several years he held the position of medical examiner of applicants for pension and was wellknown in his home city.

James Brownlee Sanford, at his home in Denver, Col., from appendicitis, March 16, aged 63. He was speaker of the house of representatives at the time of his death and was widely known throughout Colorado and the West.

John Orlando Scott, after a surgical operation in St. Vincent's Sanitarium, at Sherman, Texas, March 8, aged 66; a graduate of the University of Louisville in 1862. A surgeon of the Confederate service during the Civil war.

John Frank Gels, from pneumonia, at his home in Indianapolis, March 7, aged 35; a graduate of the Medical College of Indiana, Indianapolis, in 1891; professor of chemistry, toxicology and forensic medicine in his alma mater.

Henry Alfred Rundlett, at his home in New York, March 9; a graduate of Harvard University. He was professor of dermatology in the New York School of Clinical Medicine; an original thinker and wellknown writer.

Anton F. Blocki, from hepatic disease, at his home in Sheboygan Wis., March 6, aged 37; a graduate of Rush Medical College in 1892. A member of the American Medical Association and health officer of his home city.

Thomas McInnes, of heart disease, at Vancouver, B. C., March 16. He was formerly senator of British Columbia and subsequently lieutenant governor of that province.

Charles H. Richmond, from accidental poisoning by mercuric chlorid, at his home in Livonia, March 2, aged 63; a graduate of the University of Buffalo in 1860.

Justin G. Thompson, at his home in Angola, N. Y., March 6; a graduate of the University of Michigan in 1861 and an army surgeon during the Civil war.

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended March 18, 1904:

SMALLPOX—UNITED STATES.			Cases	Deaths
California:	San Francisco.....	Feb. 21-28.....	5	
District of Columbia:	Washington.....	Mar. 5-12.....	2	
Florida:	Jacksonville.....	Mar. 5-12.....	2	
Illinois:	Belleville.....	Feb. 26-Mar. 12.....	2	
	Chicago.....	Mar. 5-12.....	1	
	Danville.....	Mar. 5-12.....	1	
	Galesburg.....	Mar. 5-12.....	1	
Maine:	Madawaska region.....	Feb. 27-Mar. 5.....	11	
Maryland:	Baltimore.....	Mar. 5-12.....	2

Changes in the Medical Corps of the U. S. Army for the week ended March 19, 1904:

EDGER, First Lieutenant BENJAMIN J., JR., assistant surgeon is granted leave for one month.

TORNEY, Lieutenant-Colonel GEORGE H., deputy surgeon-general, is assigned to the command of the U. S. General Hospital, Presidio, to relieve Major William P. Kendall, surgeon.

GOSMAN, First Lieutenant GEORGE H. R., assistant surgeon, is relieved from duty at Fort Duchesne and will proceed to Camp George H. Thomas, Ga., for duty.

SILER, First Lieutenant JOSEPH F., assistant surgeon, is granted leave for fourteen days from about April 6.

Changes in the Medical Corps of the U. S. Navy for the week ended March 19, 1904:

FEREBEE, N. M., medical director, detached from the Navy Yard, Washington, D. C., and granted sick leave for six months—March 14.

PECK, A. E., assistant surgeon, granted sick leave for two months—March 17.

Changes in the Public Health and Marine-Hospital Service for the week ended March 17, 1904:

CARTER, H. R., surgeon, to proceed to New Orleans, La., and attend conference of quarantine officers, March 14—March 12, 1904.

BROOKS, S. D., surgeon, department letter granting leave of absence for four months from April 1, 1904, amended to read four months from April 6—March 12, 1904.

GUIERAS, G. M., surgeon, department letter granting leave of absence for three months from December 19, 1903, amended to read two months and five days from December 19, 1903—March 5, 1904.

MCMULLEN, JOHN, passed assistant surgeon, to proceed to Immigration Depot, New York, N. Y., and report to G. W. Stoner for duty—March 12, 1904.

GRUBBS, S. B., passed assistant surgeon, granted leave of absence for twelve days from March 18—March 16, 1904.

RICHARDSON, T. F., assistant surgeon, relieved from duty at New Orleans, La., and directed to proceed to Laredo, Texas, and assume command of service at that port—March 16, 1904.

FRANCIS, EDWARD, assistant surgeon, to proceed to Delaware Breakwater Quarantine and assume temporary charge of station during illness of Passed Assistant Surgeon C. H. Lavinder—March 10, 1904.

BULLARD, EDWARD, acting assistant surgeon, granted leave of absence for twenty-seven days from March 4—March 9, 1904.

MONCURE, J. A., acting assistant surgeon, granted leave of absence for thirty days from April 1—March 9, 1904.

NALL, R. P., acting assistant surgeon, granted leave of absence for seven days from March 1, 1904, under paragraph 210 of the regulations—March 9, 1904.

SIBREE, H. C., acting assistant surgeon, granted leave of absence for five days from March 15—March 12, 1904.

SIMONSON, G. T., acting assistant surgeon, bureau letter of March 10, 1904, granting leave of absence for five days from March 15, 1904, amended so as to read five days from March 22—March 17, 1904.

STANTON, J. G., acting assistant surgeon, granted leave of absence for thirty days from March 8—March 9, 1904.

THURSTON, E. J., pharmacist, granted leave of absence for seven days from March 9, 1904, under paragraph 191 of the regulations—March 9, 1904.

KOLB, W. W., pharmacist, granted leave of absence for twenty-eight days from April 2—March 14, 1904.

Appointment.

Dr. Melvin M. Hopkins appointed acting assistant surgeon for duty at Ketchikan, Alaska—March 9, 1904.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

METASTATIC OR COINCIDENTAL CANCER?¹

BY

A. L. BENEDICT, M.D.,

of Buffalo, N. Y.

Consultant in Digestive Diseases, City Hospital for Women and Riverside Hospitals, Buffalo.

In ordinary cases of multiple foci of cancerous disease, one can be designated as primary, while the secondary growths follow pretty definite metastatic routes, or extend by continuity, natural or pathologic, of tissues. In the latter growth of cases, it is, of course, often impossible to decide from the specimen of a protracted case, the exact site of the primary focus. Indeed, it is scarcely logical to designate a tumor of the liver, for example, as secondary, when it has simply extended or has been inoculated from a penetrating cancer of the pylorus. It is difficult to draw lines between the extension of a growth in the organ in which it originates, its extension to neighboring organs along normal bonds of union, its extension along pathologic adhesions, and the implantation of cancer by occasional contact, as is commonly seen on the liver and less frequently on other organs, when the original growth is at or near the pylorus and penetrates to the serous covering of the stomach.

I recall only 2 cases of cancer in which there was any question as to the relation of 2 tumors, barring the qualifications already made:

Patient, No. 49, of 1896-7, a middle-aged woman, had had the right breast amputated for cancer, about a year previously. She had some slight recurrence in the scar but died of cancer at the cardia, from gradual asthenia and inanition but without developing absolute closure at the cardia.

Patient No. 43, of 1903-4, had both breasts removed on account of cancer (microscopic demonstration), about 10 years previously. The result was perfect and certainly reflects credit on Dr. J. C. Thompson, with whom I saw the patient, for the necessity of cleaning out the axillary lymphatics was not as generally held at that time as at the present. This patient presented a hard fusiform tumor of the pylorus and obstructive dilation of the stomach. While the patient² is still alive and refuses operation, so that a pathologic diagnosis cannot be made, a tumor of the size and consistence of this, developing in a woman of 50, can scarcely be anything but cancer.

In these 2 cases the question very naturally arises as to whether the original mammary cancer was primary to the subsequent one or whether the two were entirely coincidental. I do not recall ever having seen any other cases which would come under this category, either among the cancer cases seen in private practice and carefully noted, say 100 in the last 10 years, or in cases seen personally but more or less casually, as of skin cancer referred immediately to surgeons, or in hospital wards and clinics. Just how many cases have been seen altogether, it is impossible to state with any approach to accuracy. Obviously, a case with 2 independent or apparently independent cancers, would attract attention. My friend, Dr. Roswell Park, very kindly allows me to quote him as saying that he can recall no case of visceral cancer following skin or breast cancer, which would come under this category, although a careful search of his records might perhaps reveal such.

E. Davie and L. Gallavardin³ discuss a different phase of essentially the same subject, coexisting primary cancer. They divide the possible occurrences as follows:

1. Cancers arising from distinct types of epithelium.
2. Cancers arising from the same epithelium, but themselves, histologically different:
3. Cancers arising from the same epithelium, histologically identical or nearly so, but on account of location or for other reasons, deemed not to be in metastatic relation.

They report 2 cases of the last group, the evidence of one of which is not very convincing, and state that only 7 are found in literature.

¹ Presented to Medical Society of the State of New York, January, 1904.

² This patient died about February, 1904. The tumor had not increased in size nor ulcerated into the stomach. Necropsy was not allowed.

³ Lyon Médicale, May 24 and 31, 1903.

The problem with regard to such cases as have been mentioned, is not the narrow one of perfecting a particular case history, but broadens out to cover much of the domain of cancer pathogeny and it even has a very practical bearing. For example, we may ask whether the various kinds of cancer are essentially the same disease, or whether they are entirely distinct, according to the kind of epithelium involved. This question leads to the next: Does the classification follow the embryonic membranes or, rather, can such a classification be perfected, for it certainly does not exist in satisfactory form at present. As corollaries to this question, there arise the old disputes as to whether renal epithelium is really such or whether it is endothelium, *i. e.*, of mesoblastic origin, and whether the serous surfaces of the body cavities are mesoblastic or not. In regard to the 2 cases mentioned, we can imagine a mammary, epiblastic cancer jumping to the cardia, for the esophageal epithelium is almost certainly epiblastic, but, if there is any truth in the hypothesis that cancers of different embryonic membranes are entirely distinct, we can scarcely apply a similar explanation to the case in which a probable cancer of the pylorus follows a mammary cancer. In this case, too, the lapse of time speaks for a pure coincidence, while, in the former case, the simultaneous occurrence of a recedive in the scar of operation and a cancer of the cardia, is rather suggestive of a genuine relation.

From the standpoint of the germ origin of malignant tumors, the word *germ* is used advisedly because of the widely different forms of life claimed to be causes and the vagueness of the whole matter, several interesting problems arise. Are the various kinds of cancer due to the same parasite, assuming that they are of parasitic origin, or to closely related parasites? Is there a corresponding identity of or relationship between the parasites of cancer and of sarcoma? It may be significant that cancer usually spreads by routes, which suggest a direct colonization of tumor elements, rather than dissemination of germs. Moreover, the extreme rarity of double or multiple primary cancer or of cancer following sarcoma also has a bearing on this question. Only very exceptionally does any form of malignant disease show any tendency whatever to self-limitation. In general, a disease which is not self-limited does not confer immunity against a second attack in case it is spontaneously or artificially ended without the death of the host. Just about 4% of my patients have cancer (of the digestive organs, mainly stomach) not to mention the, to me, quite extraneous occurrence of rodent ulcer, uterine cancer, etc. The United States Census of 1900 tabulates 28 cancer deaths to 1,000 from all causes, beside 3 to 1,000 assigned vaguely to tumors. At this general rate, of approximately 3%, we should expect the same number of patients cured by operation to develop a second primary cancer, not necessarily in the same part of the body. But the mortality from cancer is by no means evenly distributed throughout life. Between 30 and 34, when it first assumes notable proportions, less than 2% of all deaths are due to cancer. The ratio changes approximately as follows (United States Census, 1900):

35-39, total deaths 44,367, cancer deaths 1,417, ratio approximately 3%	
40-44 " " 41,439, " " 2,174, " " 5%	
45-49 " " 40,201, " " 2,943, " " 7%	
50-54 " " 42,666, " " 3,867, " " 8%	
55-59 " " 43,169, " " 3,652, " " 8%	
60-64 " " 48,178, " " 3,746, " " 8%	
65-69 " " 52,190, " " 3,580, " " 7%	
70-74 " " 53,073, " " 2,912, " " 5%	
75-79 " " 46,039, " " 2,037, " " 5%	

It is noteworthy, however, that in the last few quinquenniums "old age," which does not appear before the age of 60, is assigned with increasing frequency as a cause of death. Doubtless, many deaths from cancer are included under this convenient heading. Granting that the numerous errors in death certificates balance themselves, so far as cancer is concerned, and ignoring the fact that, in each quinquennium the cancer mortality must be a trifle less than the cancer incidence, on account of the cure of some patients by operation, it would appear that from 5% to 8% of all patients previously cured by operation of either sarcoma or cancer, ought to die of an independent cancer. Allowance must, however, be made for the fact that sarcoma is usually a disease of early life, and that since the

development of surgery to the present state, as regards radical operations of all kinds, not sufficient time has elapsed for the sarcoma cases to have reached the period of maximum cancer incidence. With regard to cancer, the condition is very different. Throughout the advanced medical world, there must by this time, have accumulated a considerable series of successful radical operations for cancer. Almost every surgeon has had a few such experiences, and some have published quite lengthy lists. In some series the proportions of cures, meaning freedom from recurrence after 3 to 6 or more years, has amounted to almost 50%. In some series, the reporter has modestly recorded as failures, cases in which recurrence has taken place at a distant site and after a considerable interval. Is it not worth while that these series and others should be studied from a slightly different standpoint? If even 1,000 cases of radically treated cancer with no recurrence for, say, 3 years, could be collated, we should expect 50 to 80 of these to develop independent cancer, the original region being involved *pro rata* with other regions, allowing, of course, for the actual removal of certain anatomic units, such as the breast, uterus, pylorus, rectum, etc. A "recurrence" later than 5 years and not in a well-defined area of recedive or metastasis, may well be regarded as an independent incidence. *A fortiori*, is this true of cancers of different epithelium from the original growth? Less than 50 to 80 such reappearances would not only argue that the operation had been successful in the strictest sense, but would suggest an acquired immunity. Here is an inviting field for the surgical and pathologic statistician. It is useless to speculate further in advance of reliable statistics.

"THE MODERN PHARMACOLOGY OF IRON."

BY

WILLIAM J. ROBINSON, Ph.G., M.D.,
of New York City.

To the Editor of *American Medicine*:—Dr. Wilcox's article on "The Modern Pharmacology of Iron" shows a deplorable tendency among some physicians to place half-supported theories, fanciful hypotheses and doubtful test-tube experiments above hard clinical facts, above bedside testimony. To judge from these remarks, one would think that inorganic iron has never been of the slightest value in anemia and chlorosis, but that, on the contrary, it has been injurious by causing gastric disturbances, etc. Have we not seen positive, unmistakable results from freshly and properly prepared Blaud's pills, for instance? Have we not plainly seen the cheeks and lips of young girls lose their pallor under Vallet's mass or Basham's mixture? and even the old Tinctura Ferri Chloridi does excellent service in many cases of anemia. In my opinion the true hematinic value of inorganic iron cannot be denied. The only trouble with the inorganic forms of iron is that they frequently—but not so frequently as some would make us believe—disturb the digestion, produce constipation, headache, etc. But these disadvantages have been done away with by use of the organic forms of iron, particularly the peptonate. If the experience of thousands of physicians counts for anything (and I think in therapeutics this should be our only criterion) we have in the peptonate of iron a preparation which leaves little or nothing to be desired as a chalybeate. Its hematopoietic properties cannot go unnoticed by the dullest observer, and it is free from those disagreeable features which occasionally render inorganic iron objectionable. Whether an iron preparation responds or not to McCallum's test, whether or not it gives a precipitate with silver nitrate is of absolutely no importance to anybody. Neither the physician nor the patient cares a rap for McCallum's or any other test. They all care, however, for therapeutic results, unaccompanied by disagreeable effects. In one sentence Dr. Wilcox shows the fallacy of his own reasoning, and destroys the force of all his arguments. It is when he tells us that hemoglobin is not absorbed as such, but is destroyed so soon as it enters the stomach. What form of iron could be more "organic" than hemoglobin? Dr. Wilcox tells us that, "as a matter of fact, Cloetta as early as 1896 showed that it is not absorbed as such, but is destroyed as soon as it enters the stomach. With this, the theory of the advantage of blood,

or products made from blood, for oral administration, fails." I do not agree with these conclusions of Dr. Wilcox's. But they seem to show beautifully the fallacy of the arguments and requirements, for hemoglobin is (1) of definite chemie composition, (2) does not precipitate with a silver nitrate solution, (3) does not give the blue-black color with McCallum's test. And still we are told that it is worthless as a hematinic!

THE MANUFACTURE OF SERUMS AND VACCINE.

BY

J. W. T. KNOX,
of Detroit, Mich.

To the Editor of *American Medicine*:—It is evident that Dr. Naughton, of Chicago, does not know of the existence of the law regulating the manufacture of serums and vaccine or he would not dispute, in his communication published in *American Medicine*, March 5, the correct statement of Dr. Evans on this question. If he will examine the wrapper of the next antitoxin package that he uses, he will see the words "Manufactured under U. S. Government License No. —," or their equivalent.

The Act of Congress authorizing this control of biologic products was approved July 5, 1902, and the regulations prepared by a board consisting of the Surgeons-General of the Public Health and Marine-Hospital Service, of the Army, and of the Navy, were promulgated February 21, 1903, and took effect August 21, 1903.

Under these regulations, which have the force of law, it is unlawful for any person to carry on interstate commerce in biologic products made at an establishment not duly licensed by the Treasury Department.

Licenses are issued by the Secretary of the Treasury only after inspection of the establishment by a commissioned medical officer of the Public Health and Marine-Hospital Service above the rank of assistant surgeon. The visit of the inspector is unannounced, and he is authorized to examine every portion of the premises, to see the methods used in actual operation, and to interrogate any member or employe of the firm under oath. The inspectors are required not only to investigate closely the methods of preparation, storing, dispensing, and other details in the manufacture and sale of biologic products, but to examine into the construction, and administration of establishments. Under these regulations it is plain that the government practically dictates the equipment of the establishment, and the personnel of its executive staff. Furthermore, the inspectors are required to purchase samples of the biologic products of licensed establishments, either in open market or elsewhere, as may be advisable, and have them examined for purity and potency.

Licenses are issued for only one year, but there is no specified time for inspections, and no licensed manufacturer has the slightest assurance that his plant will not be inspected 20 times a year. The inspection is not by any means perfunctory, but is carried on in rigid adherence to the letter and the spirit of the law. All this is precisely as it should be. The Secretary of the Treasury has the power to revoke any manufacturer's license for any of the following reasons: (1) Faulty construction or equipment; (2) faulty methods of preparation; (3) faulty administration; (4) impurity of products; (5) lack of potency of products, and he is required, whenever a license is suspended or revoked, to publish a circular giving the facts that led to such action.

What better regulation of this important industry could we have?

Laying all question of honor and conscience aside, is any manufacturer of antitoxin and vaccine going to risk financial ruin by marketing an inactive or contaminated product and thus courting revocation of the license, without which he could not do business for a single day? I think not. Immense amounts of capital are invested in the production of antitoxin and vaccine. The leading manufacturers have hesitated at no expense whatever to provide serums of the highest purity and potency. Their plants are open not only to government inspection, but to any member of the medical profession at any time,

and such visits are always welcomed. I have yet to see a physician, who has availed himself of this standing invitation to the medical profession and inspected a modern antitoxin laboratory, who has anything but praise for its splendid equipment, its scrupulous cleanliness, its countless safeguards against contamination, the scientific precision of its methods, and the exacting requirements for purity and activity of its products. I have yet to hear a single valuable suggestion, from any physician, of a possible improvement in any respect, although such suggestions are always asked for.

If all this is merely "dress parade," it is remarkable that no one among the thousands of physicians who visit these places annually, coming at all hours of every day, ever finds conditions otherwise. As a matter of fact, there is but one logical conclusion, and that is that the manufacturers of antitoxin do market thoroughly reliable and trustworthy products—and no other sort. But if Dr. Naughton thinks otherwise, let him call the attention of the Secretary of the Treasury to the offending firm. If he is right, he will have the satisfaction of witnessing a prompt reform, or an equally prompt retirement of that firm from the biologic business.

It is a fact of some interest that the principal producers of antitoxin gave their hearty support to the bill which afterward became the law that regulates their respective establishments. They advocated and welcomed its passage, and there is absolutely no reason to suspect that they are not now working in entire harmony with its rigorous, but wise and beneficent requirements.

REMOVAL OF A PIN FROM THE VAGINA 7 MONTHS AFTER BEING SWALLOWED.*

BY

FRANK C. HAMMOND, M.D.,
of Philadelphia.

Demonstrator of Gynecology, Temple Medical College; and Chief of the Outpatient Gynecologic Department, Samaritan Hospital.

Numerous instances have occurred in which a needle or a portion of one has escaped from various portions of the body, but I have been unable to find in literature a case similar to the following one, of extrusion per vaginam, of an ordinary pin, an inch in length.

CASE.—B. W., aged 28, single, first came under my care in 1899. She gave a history of having run into the right wrist a black-headed steel milliner's pin, which had broken off about $\frac{1}{2}$ inch from the point. Upon examination with the röntgen ray the broken pin was located, point upward, in the tendon of the flexor carpi radialis muscle. It was removed with great difficulty, and only by using the fluoroscope continuously during the operation. During July, 1900, I removed her right tube, ovary, and appendix, for inflammatory disease, and resected the left ovary. In the early part of 1902, while sewing, she ran a needle into the dorsal portion of the left thumb, over the first phalangeal articulation; it broke off about $\frac{3}{4}$ inch from the point, greatly interfering with the motion of the joint. This fragment was easily removed.

For the past few months she has been receiving local treatment for a metritis. On December 13, 1903, she complained of marked throbbing pain in the rectovaginal septum. I made a careful examination, to ascertain if there was any induration or point of suppuration, but failed to find any. While examining the left lateral wall of the vagina, just above the left levator ani muscle, I was surprised to find a sharp point protruding about $\frac{1}{2}$ inch from the vaginal wall, directly downward toward the pelvic floor. An attempt to elevate this gradually, in order to grasp it with a pair of forceps, occasioned considerable pain, causing the patient to "pull away." In so doing the object was drawn back into the vaginal wall, and was no longer palpable.

On December 15 a careful search was again made, and near the same spot in the left vaginal wall a small round object, about the diameter of an ordinary pin, was found protruding through the vaginal wall and embedded in the pelvic floor. The portion within the vagina was seized with a hemostat and pushed upward into the vaginal wall, thus disengaging the point; the object was then pulled out from the vaginal wall, the end offering a little resistance, and proved to be an ordinary pin, 1 inch in length. The pin had not undergone any change during its presence in the body.

Upon inquiry, the patient and her family remembered her having swallowed a pin some 7 months ago. At the time they considered the advisability of her taking castor-oil, and then the incident was dismissed from their minds.

* Read before the North Branch of the Philadelphia County Medical Society, January 14, 1904.

ORIGINAL ARTICLES

ABDOMINAL PAIN.¹

BY

J. H. MUSSER, M.D.,
of Philadelphia.

With the limitations that must be placed on all subjective symptoms, pain is the one which more than all others leads to the recognition and localization of disease within the abdomen. Fortunate is the physician who has the aid of a patient with clear intelligence to describe the character, the mode of onset, the localization, the direction of transmission, the association with altered function, and the many qualities of this valuable clinical expression of disease. Unfortunately, too often, when the aid of the patient is needed the most, as in the toxic period of typhoid fever, it avails not as it should.

ASSOCIATE EXPRESSION OF PAIN.

Spasm of muscles.—The occurrence of *spasm* of muscles, related by nerve supply to the organic lesion which causes the pain, as indicated by *resistance*, is of great aid in the localization of the lesion. No more valuable indication of the occurrence of irritation or inflammation exists than this symptom. Of much significance under certain

called attention to alterations of cutaneous sensibility in the distribution of spinal nerves related to affected organs within the body. Sherren¹ has called renewed attention to this cutaneous hyperalgesia, elicited by gentle friction or pinching of the skin or by the head of a pin or some blunt instrument. That such hyperalgesia may exist is well known, but the point I wish to make is, if it exists and then disappears, as may also spasm and pain, the change is of ill omen unless all other symptoms subside. The absence of, or rather the disappearance of hyperalgesia means the occurrence of gangrene or perhaps perforation. The accompanying illustrations show the distribution of cutaneous hyperalgesia in appendicitis. They are taken from Sherren's article.

PAIN IN ABDOMEN DUE TO GENERAL CONDITIONS.

The Intoxications.—I shall pass over that due to lead-poisoning, only venturing to reinforce the warning of Janeway, and speak of abdominal pain due to uremia. The French authors have long since called attention to this symptom, and many years ago I made a verbal communication to the West Philadelphia Medical Society on it. I had seen it, as had likewise the French observers, in or preceding the uremic convulsions of puerperal nephritis. In the instances under my observation the pain was in the epigastrium and both hypochondria. Only recently I was asked to see a case of alleged severe indigestion with cramps in a woman who had been

Figs. 1 and 2.—Showing the area of cutaneous hyperalgesia in appendicitis corresponding to the eleventh dorsal area of head (Sherren). Fig. 3.—Showing the "appendix triangle" of cutaneous tenderness. circumstances is its *absence*, for often it does not imply under such circumstances the absence of lesion. (a) It is wanting, of course, when there is no muscle, or perhaps very little, to undergo spasm. Hence in atrophied abdominal walls, as occur in women from overdistention, such spasm may not occur. In a case of perforating gastric ulcer with oncoming peritonitis, operated on by Keen, within 6 hours of perforation, no spasm or resistance was detected. Similar cases of such character have occurred in cholecystitis, when often for similar reasons, mural atrophy—the muscle spasm is wanting. (b) It disappears with the onset of toxemia, and hence a rapidly lessening resistance with the slightest evidence of advancing toxemia, as indicated by the expression, the tongue, the pulse-rate, the mental condition, even though the temperature falls, is of grave significance. It may be found that the leukocytes do not increase, but may even fall to a moderate height, as 9,000 to 12,000 or even less, as we also find in grave pneumococcus infections, when a moderate leukopenia may be present.

Tenderness of Cutaneous Surface. Hyperalgesia.—Hilton, Head, Mackenzie, and others have repeatedly

delivered 4 hours previously, and who had nephritis in the latter part of her pregnancy. I warned them of the oncoming of uremic convulsions and coma, which unhappily was too true 4 hours later.

UREMIA SIMULATING PERFORATING GASTRIC ULCER.

In my service of 1902, in the University Hospital, a patient was under my care for well-defined syphilis and nephritis. She had some epigastric pain, constant vomiting, and hematemesis. For reasons a gastric analysis was not made, but the vomitus did not give signs of any definite organic disease. On one occasion, while vomiting was temporarily arrested, sudden pain and shock ensued. The temperature fell to 96° and the pulse rose. I was informed perforation had taken place. Professor Frazier saw her with me a few hours later. As the toxic features of uremia appeared to be increasing, operation was deferred. Temporary recovery from the uremia took place, but death followed within a month.

At the autopsy a marked chronic gastritis, with ecchymosis and abrasions of the mucous membrane, were found, but no ulceration of the stomach. The patient narrowly escaped operation.

The next patient was not so fortunate. I saw him on an afternoon, with well-defined uremia. He suffered very much from abdominal pain. He had an inguinal hernia. I sent him to the hospital, and asked that a surgeon see him to discuss with me the relation, if any, of the hernia to the pain and vomiting. We were prevented conjoint attendance upon the

¹That portion of the symposium on abdominal pain assigned to the author—abdominal pain in general and that due to disease of the stomach, liver and pancreas. Presented to the New York State Medical Association at the meeting in Albany, January 26 to 28, 1904.

¹"On the Occurrence and Significance of Cutaneous Hyperalgesia in Appendicitis." James Sherren, F.R.C.S., Eng., *Lancet*, September 19, 1903.

case, and the surgeon, thinking I had sent him in for operation, performed it without delay. Neither incarceration nor strangulation was found, and later the autopsy showed that pain could not be accounted for by any abdominal conditions. It was evidently toxic.

Hysteria and the Neuroses.—I mention these states for the purpose of disclaiming against the accepted ideas of the frequency of abdominal pain of such origin. Too often we take refuge under the cloak of hysteria; too often such diagnosis is a confession that we are ignorant of the true cause of suffering. As our experience increases I am sure we can "run down" these so-called neuroses. The more I learn of abdominal disease the less I see of hysteria. Not many years ago I saw a seemingly well-defined case of hysteria. The patient had great pain in the region of the liver and the right shoulder, and ill-defined symptoms of gallstones. Her mother had had gallstones. Because of the general symptoms, and especially the nervous symptoms, I gave it as my opinion that the pain was probably a neurosis, and advised against an operation. Later, gallstones were passed, and soon the patient was restored to health. The nonhysterical origin of pain formerly attributed to the neuroses is strongly supported by our increased knowledge of headaches. The ophthalmologist has hunted down many of the headaches formerly described as neurasthenic, and within a few years knowledge of the mysteries and vagaries of sinusitis, giving rise to various forms of headache and neuralgia, to which belongs the headache of early morning, continuing throughout the day, "disappearing as the sun goes down," has deprived hysteria of many accusations.

ABDOMINAL PAIN NOT DUE TO DISEASE BELOW THE DIAPHRAGM.

Speaking to clinicians, it is not necessary to go further than to remind them seriatim of the many cases of abdominal pain due to extraabdominal causes. Thus we have pain due to:

1. Crises of locomotor ataxia and other organic spinal cord diseases.
2. Spondylitis rhizomelique. A case of this nature was brought to me, considered to be cancer of the liver or kidney. Many cases are referred to in the literature of the subject.
3. Caries of the vertebra.
4. Cancer of the vertebra.
5. Aneurysm of the thoracic aorta, especially located above the diaphragm.
6. Diaphragmatic pleurisy and rheumatism of the diaphragm.

A case that caused much interest was that of a robust man, who had been operated on for hemorrhoids. The man was evidently infected at the time of operation in the field of the operation. Fever and a mild leukocytosis were present. After a cold bath 3 days later the patient had a chill, severe pain in the lower thoracic and upper abdominal region, tenderness along the diaphragm, dyspnea, and slight cough. No signs of pleurisy could be brought out. When the liver was brought down by a full breath against the palpating hand it excited pain, which suggested a tender liver. There was some myalgia about the shoulders. The fever and leukocytosis persisted. Although the development of multiple abscess of the liver or subdiaphragmatic infection was suggested, the general picture was that of diaphragmatic pleurisy, or rheumatism, with myalgia in other situations, occurring incidentally in a person with an infected rectal wound. The difficulties of the case can be imagined when it is known the patient was a highly neurotic physician, who bore pain badly, and the attendants, were two brothers, who were maximally sympathetic and keenly alive to pathologic possibilities, the one a leader in ophthalmology, the other a great nose and throat specialist.

7. Pulmonary affections. Pleurisy need not further be considered as a cause of abdominal pain. Of pneumonia much more must be said. During the past 5 years, 2 or 3 cases occurred each winter, in which I was called upon to decide if the anticipated operation for a reputed abdominal affection was or was not required. My notes of 6 cases belong to children,

and it is chiefly in them we find pneumonia with symptoms of some acute abdominal affection, chiefly appendicitis. I have seen cases of pneumonia in older subjects treated as some form of liver disease, because of pain in the right hypochondrium and jaundice.

8. Cardiac affections. I can only refer to the epigastric pain of acute pericarditis, a disease so often void of symptoms and signs; of a congested left lobe of the liver in acute failure of compensation; of angina pectoris. When it is remembered in all these conditions, as well as pulmonary affections, vomiting and also flatulency may occur, we can realize possible difficulties to many.

ABDOMINAL PAIN DUE TO (A) GASTRIC AFFECTIONS.

The pain due to forms of gastritis, that due to ulcer, and that to carcinoma are so well known it is not necessary for me to enter into their consideration. I will content myself with calling renewed attention to the pain of pyloric spasm, due to hyperacidity or to gastric ulcer, and to the pain of the incontinence of retention in cases of mild or perhaps spasmodic pyloric stenosis; to the change in location of the pain due to gastric ptosis; and to the extreme rarity of gastralgia, apart from hyperchlorhydria or organic spinal disease. Alleged gastralgia is so frequently an aberrant form of hepatic or pancreatic colic, that these conditions must be definitely excluded before we rest content with the diagnosis of a functional disorder. I must take this opportunity to urge alertness on the part of the clinician to detect the earliest evidence of shock, for, as an attendant upon perforation, its significance must be realized if we want to diagnosticate the accident. Instead of "shock," in the true surgical sense, a chill, a syncopal attack, some faintness or a hurried pulse may be the only expression of a perforation.

Epigastric Hernia.—It may be proper here to say a word regarding that infrequent condition, epigastric hernia. The occurrence of epigastric hernia gives rise to symptoms which may simulate gastric affections or diseases of the gallbladder and gall ducts. Careful inspection and palpation will disclose the presence of the small subcutaneous tumors characteristic of this lesion.

(B) HEPATIC PAIN.

Only to be mentioned to remind you of the many excellent papers on this subject read by members of this organization, and that the pain of early primary affections should be heeded, for it is the operative relief of these affections that prevents the long series of secondary affections.¹

(C) RENAL PAIN.

This must be passed over with the memoranda that the recognition of renal calculi can be wonderfully aided by radiographs, and to call attention to a rare condition which simulated renal pain.

Phlebitis.—The patient had had a movable kidney transfixed by operation. Obstinate pain followed and simulated in part renal pain, although neither clearly paroxysmal nor attended by hematuria, as in renal calculus. The radiograph showed an apparent calculus in the ureter about the brim of the pelvis. Operation for its relief disclosed varicose veins in this situation with 2 or 3 phlebotitis the size of peas in the veins coursing parallel with the ureter.

(D) PANCREATIC PAIN.

Exhaustively discussed recently, time forbids my going further than to state my conviction that pancreatitis is a more frequent affection than we are wont to believe. We recognize the rarer fulminating cases that are usually fatal. Cases subacute, mild in character, and chronic cases are more common. Pain attends these affections. I fully believe, with the additional experience that comes to us, we can recognize this cause of pain.

The problem for solution in these cases of localized pain is to differentiate the various causes and to recog-

¹ See Trans. American Congress of Physicians and Surgeons, 1903.

nize if the pain is the expression of a mortal lesion, requiring immediate action to save life. For the former it requires a most careful arraignment and analysis of all the facts in the historic diagnosis, of great importance in qualifying the subjective and objective phenomena; an analysis of the symptoms, a careful elucidation of the objective phenomena and the physical signs, and an accurate estimation of laboratory findings. Alteration of function must be correlated with physical conditions. For the latter, not only must such observations be made, but alertness and unceasing vigil must be not only daily, but hourly employed, to estimate properly the degree of danger of nature's outcry, expressed in pain. With breadth of view, nicety of observation, and eternal vigilance, the true significance of abdominal pain can be appreciated, human suffering assuaged, and fortunately much oftener than formerly, life saved.

THE DISAPPEARANCE OF PAIN.

The occurrence of relief to suffering must not lull us into false safety. Such disappearance may be of diagnostic importance. Apart from termination of the disease in its natural course, such subsidence may be due to the (a) onset of gangrene, (b) to an oncoming toxemia, (c) to both, (d) to perforation of a hollow viscus, as the stomach or gallbladder or appendix, or the rupture of an abscess. If pain disappears suddenly there must be gradual, but prompt amelioration of all general and local symptoms if the patient is safe.

Pain due to gangrene is seen in appendicitis, and one must be wary, if he is not to be deluded into a false hope by its subsidence. This is all the more liable, as spasm and cutaneous tenderness may subside simultaneously. To exclude gangrene the clinical course of the disease must be closely analyzed; we must observe if the pulse-rate fall, the temperature fall, the expression improve, the tongue become moist, and the mind perfectly clear. Remember, as with gangrene, perforation usually occurs under manifestly the same symptoms. If pain subsides because of the toxemia, an incident in the course of gangrene, its subsidence is more gradual. We must, therefore, appreciate the very slightest suggestive indication in cardiac, respiratory, or cerebral action, in the temperature, the condition of the skin, and—not readily portrayed, but most important—the expression. I fear many a toxemia has crept on until the patient is within its fatal grasp because of the darkened sick-room.

As evidence of the toxemia, a leukocyte count is of great value. It is probably just as significant when it falls or remains stationary. You know in pneumonia we look upon a leukopenia with much dread, and so it is in abdominal inflammations; if the leukocytes fall or remain at 8,000 or 10,000 it is a more dangerous sign than if they rise, providing in the first instance there is no improvement locally or generally. Hence, a low white blood-cell count, without improvement in symptoms—and especially of the general symptoms due to toxemia—is very grave. I have seen practitioners relieved when with relief of pain any tumor which had been presented disappeared. It is obvious if such tumor does not rupture into the natural passages, its disappearance bodes great evil. Sometimes a tumor will disappear from one region and appear in another. I was asked to explain the occurrence of a tumor in the left iliac fossa shortly after its disappearance from the right. The original tumor, due to pus, was bound down by adhesions, and so the confined pus took the route of least resistance into the pelvis, around the rectum, and up to the opposite side.

PAIN ABSENT IN CONDITIONS IN WHICH IT SHOULD BE FOUND.

Pain is the earlier, more common, and, from its special characteristics, of greater value than the usual symptoms of obstruction when the closure is slow in progress.

The absence of pain enables us to decide upon the nature of the lesion. Thus, in a patient of Dr. Riesman upon whom Dr. Keen operated for intussusception, the symptoms were favorable until 5 days after operation, when causeless vomiting, increasing in frequency, began; at first gastric fluid alone was vomited, followed in about 4 days by the vomiting of the intestinal contents. We gave the opinion that the vomiting was due to obstruction of the bowel of paralytic origin. I quote from Dr. Riesman's notes—which he has kindly placed at my disposal—the appearances found.

Notes of Mrs. V. B.—Operation to relieve intestinal paresis causing intestinal obstruction. An incision was made on the left side, outside the first incision. On opening the abdomen no fluid escaped, but the hugely distended small intestine at once bulged into the opening. It was drawn out, and its color was found to be bluish purple. The vessels were injected; and the caliber of the bowel, that of a man's forearm, or even larger. Peristalsis was not visible, and the intestine dropped upon the table as lifelessly as if it had been that of a corpse. The distention began at about the duodenum and extended far down the intestine, ending abruptly somewhere in the ileum. At the point at which the distention ended, the bowel was contracted to about the caliber of a finger. This contracted bowel was pale and empty. There were no adhesions, no signs of peritonitis, and no exudate. On opening the distended part of the bowel, enormous quantities of yellowish, fluid, fecal material escaped and ran down upon the floor in a stream. Not a peristaltic wave could be seen. Even after the bowel had been emptied, slapping and hot applications failed to evoke any peristalsis. The colon was of normal color, was somewhat contracted, and contained—especially in the ascending portion—putty-like fecal masses that could be moved with comparative ease by applying the finger externally. The transverse colon was prolapsed as far down as the left iliac region. The sigmoid was greatly elongated. Union had taken place between the upper part of the rectum and the abdominal wall, along the line of sutures.

The absence of pain therefore in cases in which the other symptoms of obstruction of the bowel prevail is an indication that such obstruction is due to paralysis, from overdistention, from inhibition of nerve influences or from thrombosis on account of which the blood-supply is cut off.

SOME PRACTICAL POINTS IN ABDOMINAL SURGERY, WITH SPECIAL REFERENCE TO A SIMPLE TECHNIC FOR APPENDICECTOMY AND INTESTINAL ANASTOMOSIS.¹

BY

FREDERICK HOLME WIGGIN, M.D.,
of New York City.

In thinking over the various difficulties encountered in the earlier days of my professional career in an effort to find a suitable subject as a basis for my remarks this evening, it occurred to me that possibly a few words in regard to the general care of patients about to undergo an abdominal section, both before and after the performance of the operation, might prove of use to you, if serving only to impress more deeply on your minds matters that already have been well taught you by your able professors. And as diseases of the vermiform appendix and intestinal injuries are so often associated with pelvic disorders, I propose also in the course of my remarks to describe a simple technic, satisfactorily employed for many years in the removal of the appendix, and that of an easy and uncomplicated method of uniting divided bowel ends.

Many of the details about to be described may seem to some of you unimportant and unworthy of your attention, but I can assure you that they are all of the greatest importance, and, taken in their entirety, have enabled me to reduce the rate of mortality following operations undertaken for the relief of chronic intra-abdominal disorders, from 20% or more, 15 years ago, to 1% or less at the present time.

¹ Address delivered at the Annual Meeting, February 2, 1904, of the Montgomery Gynecological Society of the Jefferson Medical College, Philadelphia, Pa.

Preparation of the Patient.—When the condition for which the operation is to be undertaken is chronic, and all the time desired can be had for the preparation of the patient for the ordeal which she is to undergo, much can be done in the way of preparatory treatment, which will not only diminish the risk about to be incurred by her, but will ultimately hasten convalescence and save the operator many anxious hours. In such a case it is for the patient's welfare that the hospital where the operation is to be performed should be reached, or the trained nurse employed if the patient is to remain at home, at least a week prior to the date fixed upon for the operation. This allows the individual to become accustomed to the attendants or the environment, which is of undoubted importance, as it tends to lessen the dread and nervous tension, both of which are naturally great in such a crisis, even under the best of circumstances. During this week the sufferer should be encouraged to spend the greater part of the time in the recumbent position for the purpose of getting thoroughly rested. During this period massage may be employed to advantage in lieu of physical exertion, as it improves the circulation, promotes digestion and the general bodily welfare. So far as it is compatible with a healthy mental condition, visitors and friends should be excluded. A daily record of the patient's body temperature, pulse and respiration should be kept. An examination of the heart and lungs, and a final analysis of the urine, should be made at this time. As it is of great importance that the intestinal canal should not be distended by gas, at the time of the operation, careful attention should be paid to unloading and emptying the bowels, as well as to getting the digestive organs in good working order. This is best accomplished in my experience by giving at 10 p. m. each evening for the first 3 days, in this week of preparation, 60 cc. (2 oz.) of a mixture of equal parts of castor-oil and glycerin, to which 5 drops of tincture of opium have been added to prevent griping; this in turn is followed, on each of the succeeding days, except that fixed upon for the operation, by an enema of from 2 quarts to 4 quarts of saline solution, the rectum finally being washed out with a pint of the same solution, 6 hours before the performance of the operation. The large enema just alluded to is best given with the patient lying in the dorsal position, with her hips elevated and her shoulders and head depressed, a fountain syringe being used for the purpose, the reservoir of which should not be elevated more than 18 inches above the patient's body.

The fluid should have a temperature of 120° F. when placed in the syringe, and should be introduced into the canal slowly, being allowed to flow for 2 minutes, then intermitted for 5 minutes, and again allowed to flow for 2 minutes; after a pint of the solution has been introduced into the bowel, if the patient has an urgent desire to go to stool it is best to allow her to do so, when, after a short interval for rest, the process just described is repeated until the patient complains of a feeling of distention, intestinal colic, or nausea, which does not pass away within the 5-minute interval. By perseverance in the manner described, several quarts of saline solution can usually be introduced into the colon in the course of three-quarters of an hour, with but slight discomfort to the patient, who should be encouraged to retain the fluid for from 30 to 60 minutes before it is allowed to escape.

The administration of these enemas should be supervised by the physician, as the nurse seldom knows how to accomplish the introduction of the desired quantity of fluid into the intestinal tract, or, if she has the knowledge and experience she has not sufficient authority over the patient to effect the desired result.

The patient's diet during this week of preparation should be of an easily digestible nature and she should be encouraged to partake freely of liquids, for the purpose of getting the bodily tissues well filled with liquid.

Hot baths of 10 minutes' duration should be given daily, not only for cleansing purposes, but to promote the secretions of the skin and kidneys, special attention being paid to the navel and pubic region. The time of operation should, when possible, be arranged for a few days following the cessation of the menstrual flow, and the vagina cleansed by douching. The administration 3 times daily of a hypodermic injection of 2 cc. (30 m.) of aqueous solution of ergot, in which from 1 mg. to 2 mg. ($\frac{1}{30}$ gr. to $\frac{1}{30}$ gr.) of strychnin, or spartein 2 mg. ($\frac{1}{30}$ gr.), is dissolved, will often prove of great benefit in regulating the circulation, overcoming nervousness, inducing sleep, promoting the action of the bowels, in other words, acting as a general tonic to the system and serving to prevent the occurrence of shock at the time of operation, as has been pointed out by Livingston. The formula for the ergot solution is as follows: 4 grams (1 dr.) of Squibb's solid extract to 30 cc. (1 oz.) of sterilized distilled water, to which after the solution is made and filtered, .2 cc. (3 m.) of chloroform is added. In making these injections the needle should be pushed deeply into the muscular tissue and the fluid injected slowly to avoid pain; there need be no fear of a resulting abscess, provided the syringe, needle and solution are aseptic. The best place which I have found for making these injections, is the patient's left deltoid. While the first of these injections, in a person whose general condition is poor, is apt to induce redness and swelling of the part and cause considerable pain, subsequent injections will cause this swelling to disappear and this also can be aided by the application of a wet dressing.

In a recent case the patient, who had a weak heart and consequently feeble circulation, was so generally toned up that at the end of a period of anesthesia, lasting 2 hours, during which time a serious operation was performed, her pulse-rate was no higher than at the beginning.

If, however, circumstances do not permit us to follow the plan of preparation just outlined, the best course to pursue, in my opinion, is to give the patient the day before the operation, 60 cc. (2 oz.) of the castor-oil mixture already mentioned to be followed after it has taken effect by a large saline enema, and the next morning, about 3 hours before the operation, by a small enema of a pint of saline solution, for the purpose of washing out the rectum.

The patient's skin covering the abdomen is prepared for operation on the previous day when practicable by thoroughly cleansing and shaving it, applying a soap poultice for 4 hours over the site of the proposed incision, then replacing it, after the soap has been washed off, by a compress moistened in a 1% formalin solution, which is covered with rubber tissue. This compress is allowed to remain until the patient is placed on the operating table. It is wise to fix upon as early an hour of the day as possible, as the patient in this case has less time in which to become exhausted from want of food, or restless or nervous from the dread of what is to come. It is of great importance that, once the hour has been determined, there should be no postponement, as I have seen patients almost collapse under the extra nervous strain entailed by even an hour's delay.

If the operation is to be performed at an early hour (e. g., 8 a. m.), the patient should be given a peptonized milk punch at 11 o'clock the previous evening, and another at 5 a. m., if she is awake. If an afternoon hour has been decided upon, additional peptonized milk punches may be given to the patient at 8 a. m. and 11 a. m.

If the case is of an acute character, and an immediate operation is demanded, little more can be done than to shave and cleanse the skin in the manner already described, or the skin can be prepared after the patient is placed on the operating table by the use of a germicidal depilatory, which will be referred to again later on. If

the patient is suffering from collapse, due to intestinal perforation, an effort should always be made to stimulate her by hypodermic injections of ergot and strychnin, and intravenous injections of saline solution. If the patient does not respond to this stimulation the operation should not be performed. If, on the other hand, the patient rallies, the operation should be done with as little delay as practicable; but even in these cases it should not be forgotten that we must, to be successful, have plenty of light, assistants, and facilities for intraabdominal irrigation.

When the operation is to be performed in a private residence a room with a north light should preferably be selected. Its furniture should be removed at least 24 hours before the room is to be used for this purpose. After it has been thoroughly cleansed, the windows should be left wide open for 2 or 3 hours, then closed, and the woodwork wiped off with mercuric chlorid solution, 1 to 1,000, the floor being dampened with the same solution. A table, 20 inches wide, and 30 inches high, and varying in length, according to circumstances, will be needed, as well as several small tables or stands, a wooden-bottomed chair; all of these articles should be cleansed before placing them in the room, they should be washed with mercuric chlorid solution shortly before being used; several large pitchers, 4 or 5 basins, several platters, and a fish kettle for sterilizing the surgeon's instruments will also be needed. All of these latter articles not made of metal should be cleansed and immersed in mercuric chlorid solution until needed in the operating-room. The room should be closed after all the articles of furniture have been placed in it, and should remain so until needed. For emergency operations it is best to make no attempt to clean the room in order to avoid vitiating the air with dust; the floor should, however, be covered with a sheet wet with mercuric chlorid solution.

Several dozen towels, sterilized by boiling or by steaming in a sterilizer, and several gallons of cold and of hot water, sterilized by being boiled for an hour, will also be needed. The instruments are sterilized by being boiled 10 minutes in a 2% soda solution, except those with a cutting edge, which are immersed for 5 minutes in carbolic acid, 95%, which is then washed off.

The following satisfactory method for preparing catgut is employed by the general drug department of the City and Bellevue Hospitals of New York City:

Plain or smooth catgut: (1) The fat is removed by boiling in ether in a condenser for an hour; (2) it is then boiled in absolute alcohol for 1½ hours; (3) it is then taken from the flask with sterilized forceps and put in glass jars, containing a 1 to 1,000 chloroform solution of biniodid of mercury. In using rough catgut, each strand is wound on glass or wooden reels or is cut in desired lengths and tied up in figure 8 loops.

The chromicized (rough) catgut is sterilized as follows: (1) The fats are removed from the rough catgut by boiling for an hour in ether, and followed by soaking for an hour in alcohol; (2) the catgut is then soaked in the following chromicizing solution from 24 to 36 hours: Sodium bichromate, 3 gm.; absolute alcohol, 3 liters; then boiled over steam until the bichromate has all been dissolved. The catgut is then removed and dried by being stretched over hooks, the ends being secured by artery clamps and allowed to remain for a week, and is then tied up in figure 8 loops and boiled for 1½ hours in absolute alcohol, and is finally placed in glass jars, containing a 1 to 1,000 solution of biniodid of mercury.

The dressings are sterilized at the hospital in the usual manner by heat, but for private practice these and suture and ligature material are purchased from a reliable manufacturer.

The following method for cleansing the hands has been employed by me for the past 5 years, and it has been found entirely satisfactory:

(1) The hands are thoroughly washed in green soap and are then well rinsed off in hot water; (2) they are then immersed in 65% alcohol and allowed to remain for a few minutes; and (3) they are then washed in a solution of mercuric chlorid, 1 to 300, in alcohol. After this, all traces of the previous washing solutions are removed by immersion in distilled water. The nails are cleaned by the use of aseptic gauze, wet with alcohol.

This being rubbed along the edge of the nail readily finds its way beneath it and removes any detritus that may be there. This is much better than using any sharp instrument for the same purpose, as the gauze so used never injures any of the sensitive tissues beneath the nails and therefore lessens the opportunity for infection that sharp instruments used for this purpose sometimes offer. If there are any abrasions on the hands attention will be called to them by the smarting caused by their immersion in the alcohol and the abraded surfaces can then be cauterized with glacial acetic acid, care being taken to place the acid well between the edges of the cut by means of a wooden toothpick, and an eschar will be formed, which will thoroughly protect the underlying tissues.

After these preparations of the hands have been made, all who are to assist in the operation put on sterilized rubber gloves. However, I do not usually wear them for intraabdominal work, for the reason that even thin gloves tend to diminish the sensibility of the finger tips, which in this class of cases often have to take the place of eyes in furnishing necessary information to the operator.

The patient should be clad for the operation, so as to reduce the bodily exposure to a minimum. The anesthetic should be administered to her, when possible, before she is brought into the operating-room. If for the administration of the ether a Dawbarn inhaler (see Fig. 1) is used and the cage is filled with absorbent cotton, saturated with the fluid at the start, the mouth-piece being rapidly brought down over the patient's nose and chin, so as to exclude the air, the anesthetic state will be quickly induced; the stage of excitement will usually be avoided, and the patient will be made insensible to pain and kept in this condition for an hour with 3 ounces of ether, and for an additional hour with only 2 more ounces.

After the patient has been placed under the influence of the anesthetic agent, and put on the operating table, on which sterilized blankets have been laid in such a manner as to admit of their being folded over the patient's chest and lower limbs, leaving only the abdomen exposed, the compress previously alluded to, is removed and the skin is washed in much the same manner as that already described for the hands, and is as follows:

The tissues are well scrubbed with tincture of green soap, by means of a piece of gauze, which is preferable

Fig. 1.

to the brush ordinarily used, as there is less tendency to injure the tissues, and its use therefore lessens the danger of septic infection; after the soap has been well rinsed off, the parts are washed with 65% alcohol and this in turn is followed by a 1 to 300 alcoholic solution of

The incision in the abdominal wall is made by preference over either one of the recti muscles, but when practicable over the right, the fibers of the muscles being separated in order to reach the peritoneum, a portion of which is grasped by two pairs of thumb forceps, lifted up, and an opening made in it; by so doing the danger of injuring the underlying intestines is diminished. It is of great importance while this is going on that the anesthetist should see to it that the patient is breathing quietly and regularly; much can often be accomplished looking toward this end by removing the inhaler occasionally from the patient's face for the purpose of giving her undiluted air for a little while, embarrassed respiration and rigid muscles being due to the lack of sufficient oxygen.

For the purpose of separating the tissues on either side of the wound, catgut sutures are next inserted in the tissues forming the edges of the wound, and are passed through all of them, between the peritoneum and the fascia covering the rectus muscles. These sutures injure the tissues less than ordinary retractors, and thus leave the wound in a much better condition for primary union.

These same sutures may, when necessary, be used to close the wound temporarily, if by any accident the patient should, during the operation, come out from under the anesthetic and attempt to vomit or cough, thus preventing the forcing of the intestines out upon the abdominal wall.

The abdominal cavity now having been opened, we will assume that the appendix is diseased and requires removal, and that portion of the cecum to which it is attached is therefore brought outside of the abdominal cavity.

After the vessels in the mesoappendix have been ligated and the appendix freed from it by division of the

Fig. 2.—A, appendix; B, B', primary sutures; C, cecum.

mercuric chlorid, the parts being finally washed with sterile water. The navel is washed out with a strong solution of hydrogen dioxid, in which 30 volumes of oxygen are dissolved in water. When time does not permit of making these more or less elaborate preparations before the operation, the skin can be prepared in 5 minutes after the patient is placed on the operating table, by the use of a germicidal depilatory, several satisfactory ones being on the market. The preparation is thickly spread over the skin and allowed to remain on for 5 minutes, and is then washed off with sterilized gauze and water, the parts being then ready for immediate operation. The only objection to the use of preparations of this kind for cleansing the skin is that the chemicals of which they are composed occasionally produce an annoying irritation.

While the operation is progressing, the anesthetizer, who should always, when possible, be an experienced physician, should watch the patient constantly, and pay no attention to the operation. As soon as the reflexes have disappeared, he should raise the inhaler from the patient's face, replacing it as soon as they return. As soon as the pulse increases 20 beats to 30 beats a minute, hypodermic injections of ergot and strychnin are administered, and repeated as needed from time to time until 6 cc. (90 m.) of the ergot solution and 5 mg. ($\frac{1}{2}$ gr.) of strychnin have been given. If in spite of these stimulating injections the pulse rises to 150 beats a minute, an intravenous infusion of saline solution is at once resorted to.

Fig. 3.—B, B', B'', primary sutures; C, cecum.

tissues, the appendix is drawn through an opening made in a gauze pad, which covers the wound and protects it and the abdominal cavity as well. Before the appendix is cut off, which is done as close to the cecum as possible, 3 silk sutures are passed through the cecal tissue, one on

either side of it, and the third midway between these two (as shown in Fig. 2), and the diseased organ is then removed. Before this is done the sutures on either side are given to assistants to hold, in order that the cecal tissue may not retract into the abdominal cavity at this critical stage (as shown in Fig. 3), and also to close the opening temporarily, should the patient partially recover consciousness and attempt to vomit or cough before the opening is permanently closed by tying the sutures.

The tissues are next rendered aseptic by means of a drop or two of hydrogen dioxid, after this the edges of the wound in the cecum are turned in by an assistant by means of a pair of thumb forceps (as shown in Fig. 4,) and the middle suture is tied and its end cut off; the other sutures are then tied and before their ends are cut, the site of the wound having again been disinfected by a few drops of hydrogen dioxid, a second row of sutures, this time of chromicized catgut, No. 00, is placed in the tissues as shown in Fig. 5, for the purpose, when they are tied,

Fig. 4.—B, B', B'', sutures; C, cecum; F, forceps.

of making assurance doubly sure that healthy peritoneal surfaces are in contact (as shown in Fig. 6.)

For the further protection of the parts and to prevent the formation of intestinal adhesions which may cause trouble later, the stump of the mesocolon, when long, is attached to the cecal tissue over the wound by one or two sutures.

The method of intestinal anastomosis, to which I will next call your attention, is a modification of that of the late Professor Maunsell of London, who was the first to demonstrate that divided bowel ends could be safely united by means of sutures passed through all of their coats, and that the knots of the sutures could be placed within the lumen. This he accomplished by bringing the invaginated bowel ends out through a slit made near the end of either one of the sections of the divided bowel, before uniting them by sutures. My experience with this method of anastomosis, which I frequently had occasion to employ between 1893 and 1897 served to show me that this was an unnecessary complication, the sutures being even more easily passed and tied without making the slit and invaginating the ends before placing them, than when it was done, and that as it was safe to close the slit made in the bowel for the purpose of invaginating the cut ends by means of Lembert sutures, that one or two of these sutures could just

as well be used in closing the intestinal wound direct. To this change of technic, the attention of the profession was called in a paper read before the New York State

Fig. 5.—A, B, B', primary sutures; C, cecum; D, D', D'', D''', secondary sutures.

Medical Association, October 19, 1898, and published in the *Medical Record* for November 19, of the same year and is as follows:

Fig. 6.—C, cecum; D, D', D'', D''', secondary sutures tied.

The portion of the intestines to be excised is brought outside of the cavity, accompanied by about 6 inches of healthy intestine on either side. It is next emptied of its contents

above and below the damaged spot by passing it between the finger and thumb, and gently pressing it. The empty gut should be clamped on either side of the damaged portion of the bowel at a point 6 inches distant, to prevent the escape of fecal matter at the time of excision or during the subsequent manipulation. A useful instrument for this purpose is the McLaren clamp, or strips of gauze may be used for the same purpose. The general peritoneal cavity should be protected with sterilized pads wrung out in hot saline solution. The portion of the intestines to be removed is excised by means of a V-shaped incision, having its apex in the mesentery and its lateral borders on either side of the diseased area. (See Fig. 7.)

Fig. 7.—A, B, portion of intestines and mesentery removed; B, B, mesentery; C, C, C, lines of the incision.

The mesenteric vessels are tied before being cut, by passing a needle armed with catgut around them and tying them. The wound in the mesentery is closed by means of interrupted sutures. (See Fig. 8.)

After the divided ends of the intestines have been disinfected with hot saline solution, followed by a small quantity of 50% hydrogen dioxide in saline solution, and the resulting foam has been washed off, the proximal and distal ends are united by means of 2 sutures, which are passed through all the intestinal coats. The first suture is placed at the inferior or mesenteric border and is passed in such a manner as to include a portion of the mesentery on both sides, as shown in Fig. 9; it is then tied in the bowel and the ends are left long in order that, by means of it and the next suture to be inserted, the intestinal tissues can be held in place while the other sutures necessary to complete the union are being put in. The second suture is

Fig. 8.—C, C, incision in mesentery united by interrupted sutures.

placed directly opposite at the highest point of the superior border and after it has been tied its ends are left long and are held by an assistant, as are those of the first suture; thus the intestinal tissues to be united are held in place while the other stitches are being passed; the third suture is passed for convenience in holding the parts together between the first two and in a similar manner, its ends, however, being cut short after it has been tied; 3 other sutures are passed in the same way through the intestinal tissue which is included between the first and third and between the second and third sutures, the needle going from within outward and piercing all the intestinal coats, then back through the peritoneal, muscular and mucous coats to the interior of the other segment of the bowel; the sutures are then tied in the gut and the ends are cut off short; or these 7 sutures can be conveniently and rapidly placed by partially passing the needle through the intestinal tissues and leaving them there till all are passed, as shown in Fig. 10, when each is drawn through in turn and the sutures are tied.

When these 9 stitches have been placed and tied, half the circumferences of the divided bowel ends have been united, and the process of suturing can most conveniently be carried on

by next placing a suture half way up on the ununited side, leaving its ends long and using them to hold the tissues while the parts are sutured as before. This suturing of the parts is continued till the last one is to be placed, when a Lembert suture is substituted. If the sutures have been properly placed about an eighth of an inch from each other and from the edge and have been tied sufficiently tight, it will be found that the peritoneum is turned in and that the stitches—with the exception of the last one—are not visible (see Fig. 11.)

If some of them have been so loosely tied that the sutures can be seen on the peritoneal coat, it is best to insert a few Lembert sutures at these points. The sutured portion of the bowel should then be washed with a small quantity of a 15-volume solution of hydrogen dioxide, then with saline solution, and returned into the abdominal cavity, which should also be washed and filled with saline solution before the abdominal wound is closed.

By the method of suturing just described any portion of the intestinal tract can be united to any other portion. Anastomosis of segments of ileum and colon may be effected by this method in the following manner:

A suture is passed through all the coats of the greater and lesser intestinal segments at their mesenteric border, care being taken to adapt the border of either segment to the corresponding border of the other; this suture is tied and the ends are left long; a second suture is passed through the side of the larger segment, starting from the lumen at the point where the superior border of the smaller segment touches it and through

Fig. 10.—A, A, sutures, the ends of which are temporarily left uncut, and by means of which the tissues are held while the needles are being placed; C, mesentery.

which the suture is also passed, and is tied, the ends being left long; a third suture is passed through all coats of the highest free end of the larger segment. The location of these sutures, which are also used to hold the parts in apposition while the other sutures are being passed, and the accurate adaptation of the mesenteric border of segments, are shown in Fig. 12.

The other necessary sutures to unite the divided intestinal edges are placed in the manner already described and the anastomosed bowel ends appear as shown in Fig. 13.

Closure of the Abdominal Wound.—In closing the wound in the abdominal wall I have of recent years been in the habit of uniting the tissues layer by layer, by means of catgut sutures—drainage not being employed, except in those cases in which the cause of the infective trouble could

not be removed—as by this means there is a greater certainty of the wound being properly closed and less danger of the formation of postoperative hernia.

Before finally tying the peritoneal sutures, it has also been my custom for many years past to wash out the abdominal cavity with warm normal salt solution, 120° F. This serves to demonstrate whether or no there is concealed hemorrhage present, and when the water comes away clear, the remaining opening in the peritoneum is closed, leaving the abdominal cavity filled with the

Fig. 11.—This Figure shows the intestines after the completion of the anastomosis: A, line marking the point of union between the ends of the bowel, showing that the peritoneal coat is well turned in and that the sutures and knots are all inside the gut, with the exception of the last, for which a Lembert suture at B is substituted.

solution, the object of this being not only to lessen shock, but also to prevent the formation of adhesions, to aid in the readjustment of the intestines and omentum to their proper position, and to lessen the danger of septic peritonitis. The attention of the profession was called to this point in the technic, as well as to the fact that hydrogen dioxid, in full medicinal strength, could safely be used for the purpose of disinfecting the general peritoneal cavity, when followed by the use of the saline solution, in a paper read before the Society of the Alumni of Bellevue Hospital, November 1, 1893, entitled "Case

Fig. 12.—A, A, A, sutures, the ends of which are temporarily left uncut; C, C, mesentery.

of Contusion and Rupture of the Ileum with Peritonitis without External Wound, Successfully treated by Celiotomy and Enterectomy Followed by Circular Enterorrhaphy (Maunsell Method)," and published in the *New York Medical Journal*, January 20, 1894.

Since first employing this technic I can remember having had no case of intestinal obstruction due to post-operative intestinal adhesion, while prior to the use in this way of the saline solution in the abdominal cavity, intestinal obstruction from this cause, following

abdominal operations was a frequent source of trouble. My opinion that the leaving in the abdominal cavity of a considerable quantity of normal saline solution tends to prevent the formation of intestinal adhesions, has been confirmed by the opportunity afforded in a few instances of inspecting the intestinal tract of patients in the course of a secondary laparotomy, undertaken months or years afterward for other difficulties, upon whom at the first operation numerous intestinal adhesions had been broken up, and the technic just described, employed, and none being found to exist at the time of the second operation.

In bringing the separated fibers of the muscles together, it is important not to pull the catgut sutures too tight, for by so doing the tissues are damaged and healing retarded; one of the advantages of making the wound in the abdominal wall through either of the recti muscles is that the opening is practically self-closing.

Before the cut edge of the fascia is united by sutures, retention sutures of strong kangaroo tendon are passed and the divided edges of the fascia are then carefully united by sutures of fine chromicized catgut. If this part of the wound is firmly united, it takes the strain off the other tissues and prevents all tendency to hernia, especially during the earlier weeks of the convalescence, when the union of the tissues is comparatively weak. When these retention sutures are used, the patient may

Fig. 13.—Diagram showing the united segments of the colon and ileum. A, line marking the point of union between the ends of the bowel, showing the peritoneal coat well turned in, and that the knots of sutures are all inside the gut except the last one, at point B, which is of the Lembert variety.

be allowed to turn in bed if she is uncomfortable and wishes to do so.

The edges of the skin are next approximated by means of a subcuticular suture of catgut. When this is satisfactorily done and primary union secured, there is practically no scar.

After the wound has been closed in the manner described, the tissues are washed off with a solution of hydrogen dioxid, in full strength, which is followed in turn by a solution of equal parts of absolute alcohol and ether. This serves to disinfect thoroughly and dry the skin, and permits of sealing and protecting the wound by means of a solution of celloidin, the formula of which is as follows: Celloidin, 1 part; absolute alcohol and ether, each 4 parts. Great care must be taken not to spread the celloidin solution too widely over the tissues, as it has strong contractile powers, and continues to draw the tissues together for some time after its application. If the moisture of the skin has been thoroughly removed before the application of the solution, this dressing will prove amply protective to the wound, and no other dressing need be employed. Celloidin is not difficult to obtain, as of late years it has been used considerably for embedding tissues for cutting purposes in the pathologic laboratory. The solution being composed of alcohol and ether is naturally sterile. It is perfectly transparent, so that the slightest inflammation or suppuration in the wound is at once noticed. If too much of the celloidin

solution is employed, it may occasion severe discomfort. A little experience, however, enables the surgeon to determine how much of the solution to employ. If there is cause to fear oozing from the wound, it is best not to employ the celloidin dressing, but if it is decided to do so, it is best in such a case to protect the wound additionally by also covering it with gauze.

Beside other advantages, the use of this form of dressing prevents the discomfort and annoyances of various kinds, which attend the use of bandages which become wrinkled, causing irritation of the skin, or even serious bedsores; they also become soiled, by urine or feces, thus adding to the discomfort of the patient and also to the danger of possible infection. If all goes well the celloidin remains on 10 or 12 days, its transparency as already stated allowing the wound to be thoroughly inspected from day to day.

After-treatment.—Before the patient is removed from the operating table it has been found advantageous for the purpose of preventing the annoying gastritis, which frequently follows the administration of the anesthetic, to wash out the patient's stomach with saline solution, and for the purpose of preventing the occurrence of intestinal paresis; in all cases, except those in which a complete intestinal anastomosis has been done, to place in the stomach, before withdrawing the tube, 4 ounces of saturated solution of magnesium sulfate, it being mechanically difficult for the stomach to throw off so small a quantity of liquid, the result generally being that the patient's bowels act within a few hours, and all danger from this source is over.

If during the operation stimulants have not been required to any extent, a hypodermic injection of the solution of ergot, already mentioned, combined with strychnin and spartein, or without either, according to the exigencies of the case, will tend to prevent the nausea, which frequently follows the administration of the anesthetic, and it will also tend to make the patient comfortable by quieting the nervous system. These injections of ergot may be repeated advantageously from 3 to 8 times each 24 hours, according to circumstances, until the patient becomes comfortable and the temperature and pulse become normal.

The patient is now returned to her bed, which has previously been heated by hot water bottles, which should, however, be removed before the patient is placed in it, as even with care, blisters and burns are often produced by contact with them, even when only moderately heated on account of the patient's sluggish circulation; she should be placed directly within the folds of a blanket. When a quantity of hot saline solution is allowed to remain in the abdominal cavity, the patient generally leaves the operating table in good condition, and with a warm moist skin. If the patient's pulse is weak and rapid, it is wise to raise the foot of the bed somewhat. There is, however, usually little shock, unless there has been much loss of blood during the operation.

During the first 12 or 18 hours following the operation it is usually best not to allow the patient anything by mouth, except a little warm water from time to time. If ether has been administered intelligently in small quantities, and in the manner previously described, there will generally be little or no vomiting or nausea. If the demand for fluids is urgent, which is seldom the case when saline solution is left in the abdominal cavity, it is probably due to gastric irritation, and can usually be successfully combated by 2 or 3 large doses of bismuth salicylate given at intervals of 4 hours. The comfort of the patient during this early period of convalescence will be promoted by passing a rectal tube 3 or 4 inches into the rectum every 4 hours, leaving it in place for a little while, and before its withdrawal placing in the bowels from 10 ounces to 16 ounces of normal salt solution at a temperature of 120° F.; this the patient should be encouraged to retain for a time, as it will tend not only to pro-

mote the passage of gas, but at the same time will serve as a stimulant to the circulation, kidneys, and skin.

As has already been stated, when an intestinal anastomosis has been effected, no cathartic should be placed in the stomach when it is washed out on the operating table, or administered by mouth for 72 hours thereafter; dependence being placed on the saline enemas, already alluded to, to move the bowels, if it is desired to have them act before this time.

Concealed hemorrhage, which manifests itself during the first 24 hours by rapid pulse-rate and increased rapidity of respiration, a falling body temperature, dilation of the pupils, and clammy perspiration, should never occur when catgut is the material used to tie off the vessels, if the ligatures are carefully placed by passing them through the tissues with a needle and the gut is taken directly from absolute alcohol in which it is preserved and tied first with a single knot, and then with a double knot, as pointed out by Frederick, of Buffalo; this prevents the gut from becoming loosened and untied, and is the reverse of the usual manner of tying silk when used for a similar purpose.

If, 15 hours after the performance of the operation, the nausea following the administration of the anesthetic continues, in spite of the treatment outlined, and the patient has not had a movement or passed gas by the bowels, and her abdomen is beginning to be slightly distended, intestinal paresis should at once be thought of, and a seidlitz powder administered in the following manner:

The contents of the blue paper having been dissolved in a tumbler full of water, the contents of the white paper is dropped upon the surface of the solution at the time the patient is ready to drink it, a warning having first been given to the patient of the importance of retaining the liquid. The advantage gained by the administration of the powder in the above described manner is that the acid dissolves slowly, the solution thus maintaining its agreeable taste till it is swallowed, and also that some of the gas being generated in the stomach exerts a counterpressure on the intestinal contents and thus helps to overcome the existing reversed peristaltic current, and to start it once more away from the stomach and toward the anus. The physician should personally supervise the administration of the remedy and remain with the patient until the bowels act, for the time is a critical one, and in a few hours the patient will either pass safely out of the threatened danger or be beyond the hope of recovery. If the saline is retained by the patient, 1½ hours later a tumbler full of hot peptonized milk will often cause the bowels to act freely, and when this occurs all danger is usually over, the patient ceases to regurgitate the stomach contents, passes gas by the bowel, and in a few hours is ready to take 8 ounces of peptonized milk every 3 hours. Should the patient reject the saline I have found it advantageous to administer a second powder within 15 minutes, or while the patient is somewhat exhausted by the act of rejecting the first, the importance of retaining the solution being explained again to the patient, who often must be ordered in rather an imperative manner to endeavor to retain it. The second effort is usually successful, provided the condition has been promptly recognized and treatment instituted. If, however, it is not, a turpentine enema should be given, or one consisting of 6 ounces of saturated solution of magnesium sulfate and 2 ounces of glycerin.

The onset of peritonitis is indicated by a gradual but persistent rise of pulse, increased frequency of respiration, beginning on the second or third day, accompanied by a sharp and persistent pain, gradually increasing in intensity, the body temperature being elevated or not. If the pulse-rate rises and remains, in spite of our efforts, above 120 a minute, the outlook is generally unfavorable. Much may still be done, however, by the judicious use of ergot, strychnin, and other stimulants and

food, also by the introduction of large quantities of saline solution into the system by either mouth or bowel, as well as by promptly recognizing and evacuating accumulations of fluid in the abdominal cavity, whether purulent or otherwise, the pressure from which alone often causing embarrassment of the lungs and heart, and by keeping the bowels well opened by the daily use of castor-oil or enemas.

Infection of the abdominal wound usually manifests itself by the occurrence of a secondary rise of body temperature, 4 or 5 days after the operation has been performed, and should be treated by opening the wound, washing the parts with hydrogen dioxid and following this by the application of a wet dressing. The best treatment for an infected or sluggish wound is to irrigate it with saline solution, to which tincture of myrrh and hydrozone have been added in the proportion of 1 to 16 each, followed by the application of gauze soaked in a mixture of equal parts of Peru balsam and castor-oil.

The wound, as a result of this treatment, will soon be in a condition to have its edges approximated by secondary sutures.

While the various symptoms described have individually to be considered, and their meaning weighed, they also have to be considered collectively, and in judging of the gravity of the patient's condition, the facial expression is of the greatest value to those who have had experience. A depressed and anxious countenance generally denotes a grave condition, and a cheerful one, even if accompanied by an elevation of the pulse and temperature, that the condition is not serious.

In conclusion, I would impress upon your minds that rest and care, looking to the regulation of all of the patient's bodily functions prior to the performance of an intraabdominal operation, lessen the danger during and following it, often changing the convalescent period from a time of great discomfort into one of peace and rest.

And that in the long run the most successful surgeon, other things being equal, will be the one choosing the simplest technical methods and most willing and able to look after all that concern's his patient's welfare.

TORTICOLLIS AND SPINAL CURVATURE DUE TO EYESTRAIN.

BY

GEORGE M. GOULD, M.D.,
of Philadelphia.

The report of the following case should prove of interest alike to the general physician, the orthopedic surgeon and the oculist. To the first because the patient was of tuberculous parentage and it had been feared that she would develop tuberculosis, if she already did not have the disease. The symptoms simulating tuberculosis were soon found to be caused by a false position of the head. In the course of the treatment of eyestrain, it was discovered that the wry-neck had caused spinal curvature. By accident it was learned that the torticollis and spinal curvature were both due to an odd axis of astigmatism. The details are as follows:

In 1901 a young woman of 18 years of age, was sent to me from a distance because of severe and protracted headaches, bloodshot eyes, blepharitis, and pains in the eyeballs. The state of her health had compelled her to quit school. She had breakfast-anorexia, and a poor appetite generally. I found her static refraction was:

R. + Sph. 2.50 + cyl. 0.37 ax. 90° = 20/20 +
L. + Sph. 2.25 + cyl. 0.50 ax. 90° = 20/20 +

without muscle imbalance.

There was no improvement in her general or special ocular symptoms by the use of the glasses that I had ordered. On account of the tuberculous history of her parents and of a continuous cough, I advised that she should be placed under the care of a general physician, to live out of doors, etc. I did not suspect that I had made a blunder in my prescription for glasses. Two years later, i. e., in 1903, I could not find that any

change was required in her glasses, although I made a careful retesting, again under mydriasis. I had evidently repeated my error, however, of two years previous. I then noticed a drooping of the right shoulder, an inclination of the head to the right and downward, a flat chest, round shoulders, etc. (Fig. 1), and urged that the girl should be placed in the care of a teacher of physical training, to correct these vicious conditions. This was finally agreed to, and Miss Devennie, of Philadelphia, took charge of her. As a result of her examination she found the spinal curvature, which is shown in Fig. 2. There was no disease of the bone, and an orthopedic surgeon was not called in. Within a few days after systematic gymnastic training was begun the patient returned to my office with a spontaneously-made and original discovery. It was announced in these words: "Doctor, when I straighten up and hold my

Fig. 1.

head straight as you and Miss Devennie want me to do, I cannot see well." The explanation of the failure of the glasses to cure the headaches, etc., was at once plain, and still clearer the reason for the spinal curvature and torticollis. I had undoubtedly failed in accuracy to correct some odd axis of astigmatism. Painstaking testing now showed that the astigmatic axis of the right eye was 90°, with the head slightly canted down and to the right, and that it was 75° with the head erect. In previous refractions I had stupidly allowed the girl to hold her head in this way while refracting the right eye. Immediate change of the right lens in her spectacles from 90° to 75° (there was no change in the amount of ametropia, and none in the axis of the left eye), produced the noteworthy result that she can now see well only with the head erect. When holding the head canted down and to the right, as formerly, she "cannot see well." The habitual position in reading is shown in Fig. 3. While taking gymnastic exercises her teacher has noticed, without the girl's knowledge of the fact,

that, being without the glasses, the head takes its former abnormal position and the right shoulder droops, the back becomes more humped, etc. With the glasses on, the erect position is at once assumed. The proof seems beyond question that the torticollis, drooping shoulder, bent back, flattened chest, and

Fig. 2.

spinal curvature, are all the product of 18 years of the enforced habit of inclining the head in order to obtain clearer vision with the right eye through an axis of astigmatism differing 15° from that of the other eye in symmetry.

Moreover, since the change in the right lens was made, and the erect position assumed, the patient has been suddenly and entirely relieved of a pain in and about the sternum, which for many years had given her much uneasiness. This pain was not constant, but came on with exercise, deep breathing, coughing, etc. She had not spoken of it much, because of the disinclination to allude to the "consumption" which it was supposed to indicate.

It is needless to add that the headaches, anorexia, etc., which the former glasses failed to cure have also disappeared with the placing of the right axis at 75° instead of 90° . I think this is primarily due directly to the correct lens, which has abolished the reflex, but of course there is a secondary result from the proper position of the body, increased lung-capacity (which is demonstrated), better oxygenation of the blood, etc. The spinal curvature is rapidly disappearing, the head is habitually held erect, the shoulders and back are almost normal and the general health perfect.

The following additional case is confirmatory evidence of the theory:

A patient, herself a professional physical training expert, a woman of 25, of perfect physical form and health (except occasional ocular reflexes) tells me that, for several years, at about the age of 16 to 19, she had a decided curvature of the spine, diagnosed by excellent physicians. She also had torticollis. By the most careful and long-continued physical training under experts in physical culture the head was brought to a normal position and the spine made perfectly normal. She now has a very high degree of astigmatism both axes at 170° —a defect which would not allow binocular fusion with the head in the normal position. I take it that the results of the several years of arduous training could have been more easily and quickly secured by cylindric lenses at proper axes. Several girls in the same col-

lege class with my patient had torticollis and spinal curvature, which has persisted despite all efforts and training, and one of these at least has endured years of wretchedness from headache, sickheadache, etc. (eyestrain reflexes), while her wry-neck and curvature have become worse. I have also had a case that cannot be described as one of torticollis, but rather of abnormal position of the head. This patient, a man of 25, has held his head in the position to be described so long as he can remember. The head is thrown backward in a constrained and unnatural position, and also to the left side. In refracting him it was impossible for me to get him to hold the head downward and forward in a normal position. In a second or two after placing it so, it would return to the retracted and noticeably unnatural poise. This led me to examine the ocular muscular imbalance more accurately, and I found that most rare anomaly which has been called "cyclophoria." He had never had diplopia, but the axis of vision of one eye was so far below and to one side of that of the other that it was only by this abnormal and constrained position of the head that they could be fused and diplopia thus prevented. The patient said that this position of the head prevents him in walking from seeing the ground for some distance in front of him; it also necessitates his holding his book or paper very high. He has never had the usual reflex symptoms of eyestrain, and has only a moderate degree of compound hyperopic astigmatism without anisometropia. Prisms equal to 6° base down right, axis 100° , fused the two images, added greatly to the clearness of vision, and enabled him to hold his head in a normal position. He was right-eyed, with equal acuity of vision. He had never had any spinal curvature.

In order to illustrate the ease with which the ocular cause may be overlooked, I will epitomize the case history of another patient:

A young man was brought to me in 1901 by his father. He

Fig. 3.

had evident symptoms of eyestrain. I found the following error of refraction:

$$\begin{aligned} R. &- S. 0.25 + C. 5.25 \text{ ax. } 75^\circ \\ L. &+ S. 0.50 + C. 6.00 \text{ ax. } 75^\circ \end{aligned}$$

This ametropia was properly corrected. The father incidentally remarked that the boy had spinal curvature. I had noticed that he had a malpoise of the head, but I was too stupid to recognize its significance. I recommended that the boy

should be placed in charge of a good orthopedic surgeon. Dr. H. Augustus Wilson was consulted, verified the diagnosis of spinal curvature, and, by proper treatment, the spinal abnormality and malposition of the head have entirely disappeared. Dr. Wilson had also in mind the possibility of the spinal trouble being due to the eyes, but as the patient was referred by an oculist, he undertook the correction of the defect by orthopedic methods only, and said nothing to me of the possible cause, the ametropia. There is no doubt as to the truth of the theory in this case, and almost none, also, as to the fact that without the correction of the ametropia there would not have been so speedy a cure of the spinal malcurvature.

The possible influence of eyestrain in producing torticollis, so far as I have been able to find, was first suggested by Dr. George T. Stevens. In the June, 1877 number of the *Archives of Ophthalmology* he speaks of the tendency of patients with insufficiency of the superior or inferior recti muscles of the eyes, to carry the head turned to one side. He says that once become permanent, tenotomy of the sternocleidomastoid muscles is necessary, but that "in a much greater number the muscles of the neck will regain equilibrium either speedily or after some time when once the vicious ocular tendency is removed." But no cases are reported by Dr. Stevens, and none definitely referred to. I shall later point out what seems to me the fundamental error in Dr. Stevens' interesting and valuable thought.

In the *Transactions of the American Orthopedic Association* for 1889, Dr. E. H. Bradford reports a case of "Functional Torticollis from Defective Eyesight." The same case is reported by Dr. Wadsworth from the ophthalmologist's standpoint in the *Transactions of the American Ophthalmological Society* for 1889.

Case of Drs. Bradford and Wadsworth, of Boston.—A bright boy of 14, had had wry-neck from infancy, together with lateral spinal curvature to the left. There was no permanent contraction of the muscles of the neck. Although there was a well-marked convexity of the spine to the left, the vertebrae were apparently normal. Long-continued attempts, chiefly of a gymnastic kind, had been carried out in Sweden in the attempt to normalize the position, but without any effect upon it. Dr. E. H. Bradford referred the patient to Dr. Wadsworth. The left eye, from childhood, "rolled up" and the head was tipped to the right. The right shoulder drooped. There had never been diplopia. "Only when the eyes were turned strongly down and to the left, while at the same time the head was inclined forward and to the right, and rotated a little to the right, did he apparently get binocular fixation." Prisms, amounting together to 20° to 25° base down L., base up right, apparently gave binocular fixation with the head nearly in the normal position. Fundus was normal. Vision each eye was $\frac{1}{2}$. Vision under homatropin R. or L. with +0.75 = $\frac{1}{2}$ +. Two unsuccessful attempts to tenotomize the left superior rectus were made, but success was attained at a third trial. The result in one month, was that the boy was much straighter both in head and trunk, and improving. The left eye now turns down as far as the right. Stereoscopic vision was, however, still impossible, and the cover-test showed deviations. A month later there was still drooping of the right shoulder, and the head was slightly tipped. Vision R. with 1 Cyl. 0.50 = $\frac{1}{2}$ +, L. with +0.50 = $\frac{1}{2}$ +. Dr. Wadsworth adds:

"The fact that the distortion did, to all appearance, render binocular fixation possible in one position of the object, led me, in the absence of other discoverable cause to think this supposition (of the ocular etiology) probable. It is within the bounds of possibility also that in earlier life the twisted posture gave binocular fixation over a wider area, and, therefore, for a larger part of the time, and that the posture once become habitual, occasional binocular fixation only was needed to maintain it in permanency. The rapid improvement that took place after tenotomy appears to sufficiently confirm the correctness of the theory." Dr. Bradford says: "To attain binocular vision the boy is obliged to hold the head on one side."

Case of Dr. Lovett and Dr. Cheney.—A boy of 3 years of age had turned his face to the right side for about 6 months. The head resisted manipulation, to place it erect, although the turning was not constant. When looking attentively at any object the child always turns the head. Dr. Cheney found slight convergence of the right eye: Diplopia could not be diagnosed in a child of the age of this one. There was chronic choroiditis of both eyes, with central choroiditis of the right sufficient to impair vision. Idiopathic torticollis seemed the necessary diagnosis of the orthopedic surgeon. Dr. Cheney performed tenotomy of the right internal rectus. There was improvement noted in a month in the position of the head, although there still remained some convergence of the eye, and another operation would probably be necessary.

*Three Cases of Dr. S. D. Risley, of Philadelphia,*³ as re-

ported in the discussion of Dr. Wadsworth's paper. Dr. Risley said:

"I have had the opportunity of studying three similar cases, and do not know of any recorded case. The first was seen in 1880, age 15, a stalwart lad, the son of a physician. The head was carried strongly to the left side, both in reading and walking, but could be readily and voluntarily brought to the upright position. Notwithstanding this fact, a general surgeon had advised a tenotomy of the muscles of the neck. The boy volunteered the statement that when he held his head erect his vision was impaired. His father, therefore, brought him for advice about the eye trouble. In the habitual position the boy enjoyed binocular vision sharpness 20/xx, while in the erect posture the letters were confused by vertical diplopia, which was, however, corrected at 20 feet by a 3° prism placed with its base down over the right eye, and V. = 20/xx. The refraction was for O.D.H. = 1 D., O.S.H.As. = +.50 C + .50 cy. ax. 90°. A tenotomy complete of the right superior rectus was done under ether, assisted by Dr. Randall and the boy's father. The result was to relieve the faulty position in which the head was habitually carried for several years. He was placed as accountant in a badly-lighted counting-room in 1887, and soon developed asthenopia and a return of the faulty posture, but allowed a year or more to pass without seeking advice. I then found not only a return of the former conditions, but a marked lateral curvature of the spine. A complete tenotomy of the left inferior rectus was done, and subsequently a second division of the right superior rectus, which, together with a correcting glass, relieved the asthenopia, but did not affect the ungraceful carriage which was now produced by the permanent deviation of the spine.

"In the other cases, one was relieved by prismatic glasses without operation both from the faulty posture and the asthenopia; the other by a double tenotomy and the subsequent use of weak prisms. It had not occurred to me, however, to place these cases in the category of torticollis."

Case of Dr. J. K. Young, of Philadelphia.—A woman of 30, in 1891 had torticollis, which was cured by a prism of 3° Base down in the right lens. The asthenopic symptoms were also improved. The glasses ordered were:

R. Prism 3° Base Down.
L. + Sph. 0.25.

The head was turned down and to the right. It is not known whether there was any spinal curvature. There was evidence of astigmatism in the right eye, but it was not corrected. In his "Orthopedic Surgery," Dr. Young says: "Compensatory torticollis is met with in lateral curvature, but in many instances of association of these two conditions, the wry-neck will be found to be primary. Of a compensatory nature also are those cases of wry-neck developed from irregularity of the sight of the two eyes—a condition termed by Quignot, *torticollis oculaire*, a not infrequent condition in the writer's experience." And there is another reference under "Treatment," p. 258: "When dependent upon ocular defect the insufficiency should be corrected with prisms, tenotomy only being performed when the deformity amounts to 12° or more. In a recent case of the writer a 1° prism base down, in the left eye corrected the insufficiency, and with the proper correction for hypermetropia relieved the torticollis."

We thus have the following, which so far as I can learn, are all the cases reported or alluded to in literature, as showing that eyestrain may cause torticollis and spinal curvature:

1. Statements of Drs. Stevens and Quignot, which must have been founded on cases observed.
2. Cases of Drs. Bradford and Wadsworth.
3. Case of Drs. Lovett and Cheney.
4. Three cases of Dr. Risley.
5. Cases of Drs. Kilburn and Lovett.
6. Case of Dr. Young.
7. Cases of Dr. Gould.

8. The case of Dr. E. G. Brackett, of Boston, not published, spoken of in a letter to me—"of a child I have just seen in our hospital clinic with a distinct though not severe torticollis and lateral curvature; it has a paralysis of the external rectus, from which the child has developed the necessary habit of holding its head to one side."

In the "Orthopedic Surgery" of Bradford and Lovett, second edition, occurs this sentence: "Ocular torticollis may occur when a difference in the plane of vision of the eyes exists, or when a difference in power of 2 eyes is present." In a personal letter to me, Dr. Lovett writes as follows:

My attention was first called to this subject by Dr. H. W. Kilburn, of Boston, who began referring cases to me when lateral curvature, in his eyes, was associated with unequal astigmatism. From an orthopedic point of view the cases have done very well, and I think I am speaking correctly in saying that it is

¹ Transactions American Orthopedic Society, Vol. II.

² Transactions American Ophthalmological Society, 1889, p. 384.

Dr. Kilburn's opinion that the astigmatism of some of them at least was helped by the improvement of the lateral curvature.¹ Now that lateral curvature is more generally regarded as a purely static problem, it is obvious that anything that causes the head to be held to one side is possibly a factor of importance and any inequality of the vision of the two eyes, as well as an inequality of the two ears, is an important cause.

Dr. Cheney, in the report quoted, says:

The resulting deformity in these cases of muscular insufficiency is due to the fact that the subject suffers from diplopia, and that the double vision can be corrected by turning the normal eye so that its visual axis is made parallel to the visual axis of the deviating eye. To give an illustration, we will suppose a patient, with a marked insufficiency of the rectus externus of the right eye, and as a result a converging strabismus of the eye and diplopia. If the left eye is now turned outward, so that its visual axis is made parallel to the visual axis of the right converging eye, the double vision will, of course, be corrected. If a patient wishes to see an object in front of him he must look directly forward with the left eye and see double; or, what is better, he can keep both eyes turned to the left, at the same time turning the face toward the right shoulder, and see the object single. The turning of the face to the right, if continued for any length of time, would naturally result in more or less contraction of the muscles of the neck and a permanent torticollis.

In the case of Dr. Young, also, the only thought was of prisms for the "insufficiency" for the relief of the torticollis. The quotation from the "Orthopedic Surgery," of Bradford, and Lovett speaks of the ocular cause as being "a difference in power of the two eyes," but it is plain that only the muscular powers of the external ocular muscles was referred to. The theory of the orthopedic and ophthalmic surgeons was that heterophoria alone caused the trouble. The ametropia was not considered. This fact is made clear by the advice and practice only of tenotomy of the ocular muscles, or by the prescription of prisms. But it is also manifest in the fact that the ametropic conditions are held so nonsignificant as to be inaccurately reported or comparatively ignored. In one case the refractive error was found to be + Sph. 0.75 in both eyes, and a month later it was put down as R. + Cyl. 0.50, no axis given, and L. + Sph. 0.50. The astigmatism could hardly have developed during the month, and the designation of the axis of astigmatism would have proved the most important fact of the case.

In the case of Drs. Bradford and Wadsworth the tilt of the head was to the right, and the left eye was the one that "rolled up," and that was tenotomized. In that of Drs. Lovett and Cheney the head was turned to the right with convergence, and tenotomy was performed on this eye. In Dr. Risley's case the head was carried to the left side. The astigmatism was in the left eye, but the right superior rectus was the muscle cut, followed later by cutting of left inferior rectus.

In my case the right was the clearer seeing eye, the head was canted to the right and the right had the unsymmetric axis of astigmatism which caused the false position. There was perfect muscular balance in this case, *i. e.*, 1° of 20-foot esophoria.

Almost every case of refraction demonstrates the truth that the "insufficiency," heterophoria, and even the heterotropia is caused by ametropia. If, therefore, the eyestrain caused these cases of torticollis and spinal curvature the method of treatment should have been by correction of the conditioning ametropia, instead of by surgical operations upon the secondarily affected external muscles, or by prisms, bases up or down. The earlier in life it is done, the more surely the cure or prevention. There is proof of this in the fact that the tenotomies in none of the cases were successful. In the first case there were deviations by the cover-test, stereoscopic vision was impossible, and the head and shoulder still drooped. In the second, convergence still remained after operation, and a second operation was advised. In the third case, two operations were performed, a correcting glass relieved the asthenopia, but the ungraceful carriage and deviation of the spine persisted.

In the fifth case there was perfect cure of headaches,

ill-health, pain in the chest, the tilt of the head, and progressive straightening of the spinal curvature solely by means of the proper astigmatic lens of the affected eye and side.

My own error in not placing this axis correctly cost my patient two years of continued reflex suffering which might have been avoided, made still more inveterate the chronic malposition of head, shoulders, and spine, did not relieve the bad general health, and postponed for two years the discovery of the cause of all these conditions. The diagnosis of the deviated axis of astigmatism was made more difficult by the patient's habitual tilt of the head, and the detection of such a slight asymmetry of the astigmatic axes, in low defects, is already sufficiently difficult. Hence, I am inclined to think such misplaced axes exist more frequently than we suspect, and that they were probably present in at least some of the foregoing cases.

The fundamental and conditioning cause of all such cases is any abnormalism that requires the habitual carrying of the head in an inclined or twisted poise. Consequently when one ear is deaf or partly so, the constant bending of the head so that the hearing ear is directed to the front, may cause resultant torticollis and secondary spinal curvature, as pointed out by Dr. Lovett. Dr. Brackett writes me:

I have also noticed among the blind children in the kindergarten a very large percentage of curves. For instance, at one time, among 36 there were 10 or 12 who had distinct curvatures. Most of these were not completely blind, but were able to see light with one or the other eye, and on account of which they held the head turned to one side, as if in the attempt of seeing a little light in walking.

I wish, lastly, to mention an important causal factor—the existence of right-eyedness or left-eyedness. I am convinced that every one is either right-eyed or left-eyed by inheritance or habit; *i. e.*, uses one eye, usually the one with better or specially trained vision, for certain purposes, exactly as one is right-handed or left-handed. Most people, I think, are right-eyed, but by no means in the large proportion they are right-handed, because of the many accidents of ametropia, which may make the left eye the better seeing eye. The fact that from savage times to the latest military regime of civilization marksmanship with bow or gun is carried out with the "sighting" by means of the right eye demonstrates that the left-eyed exceptions are comparatively few. In my case here reported the right eye, although slightly the more ametropic, was the one most relied on, and its vision was much the sharper. Hence the new astigmatic lens at axis 75° compels the patient to hold the head erect and turning it downward and to the right, as formerly, obscures vision so much that she says she "cannot see."

The practical lessons are so evident that they scarcely need stating:

1. Habitual abnormal position of the head is frequently the cause of spinal curvature.
2. These abnormal positions may be due to some error of refraction, which necessitates the torticollis, wry-neck, cant, or depression, in order to secure clearer vision.
3. The error of refraction is usually a slight asymmetry of the axes of astigmatism, whereby the clearer-seeing or most-used eye (usually the right in right-handed persons), has an axis 10° or 15° to either side of 90° or 180°, *i. e.*, at about axes 75°, 105°, 165°, or 15°.¹
4. The heterophoria, which has been the supposed cause of the functional torticollis, etc., is itself, usually a result of the refractive error, proper correction of which, at a sufficiently early age, cures the heterophoria, the torticollis, and the spinal curvature.

¹ Since this paper has been in type I have discovered several more cases in which a lifelong tilting of the head has been demonstrated as due to these slightly asymmetric axes. I am inclined to think them much more common than supposed, and that the astigmatic cause so easily overlooked in careless refraction work is a more common source of wry-neck than orthopedic surgeons and oculists have suspected.

¹ This is, of course, impossible.—G. M. G.

FATAL PULMONARY EMBOLISM FOLLOWING ASCENDING PHLEGMASIA ALBA DOLENS.

BY

JOHN G. SHELDON, M.D.,

of Telluride, Colorado.

CASE I.—Normal labor; slight fever and abdominal pain and tenderness on the fourth day; temperature normal on the twelfth day; left ankle swollen and tender on the fourteenth day; symptoms very mild until the twenty-second day, then sudden death—doubtless from pulmonary embolism.

Mrs. B., aged 32, Italian, gave birth to a healthy male child. The pregnancy and labor were normal. On the fourth day, following labor, she complained of some abdominal pain and distention. The attending physician found the temperature 100° F. and the pulse-rate 92. A cathartic was given and a douche ordered to be given by the nurse. The patient did very well, and on the twelfth day there was no tenderness and the temperature was normal. The pulse-rate, however, was 84 per minute. On the fourteenth day the patient complained of sudden pain in her left calf. At this time examination showed some edema and swelling of the left ankle. The posterior surface of the left calf was tender on deep pressure. The temperature was 100° F. and the pulse 98. During the next 5 days the patient remained in about the same condition. The swelling and edema extended to the knee, but the pain was slight. The patient's general condition seemed good. The temperature remained about 99° and the pulse-rate about 100. I was called in consultation on the nineteenth day. At this time the patient seemed in good spirits and complained of nothing except the slight pain and tense feeling in the left leg. The left lower extremity was considerably swollen and was firm and pitted on pressure. The limb was not cyanotic. Slight tenderness was present everywhere below the knee. The thigh appeared normal, excepting slight tenderness over the internal saphenous vein. The heart and lungs showed no abnormal changes. The abdomen was not tender or distended. A vaginal examination was not made.

I told the physician and the family that the patient was suffering from a rather unusual, but mild form of milkleg, and that I expected her to recover without complications. I informed them that doubtless the leg would be enlarged and weak for some time, but I did not think the condition sufficiently severe to warn them of the possibilities of pulmonary embolism. On the twenty-second day the patient cried out suddenly, gasped a few times for breath, became slightly cyanotic, and died. A postmortem examination was not made.

In this case the patient was never out of bed from the time of the birth of her child; the affected leg was never subjected to rubbing; and during examinations special care was used in handling the limb.

CASE II.—Primipara; labor normal; puerperium normal till twelfth day; then pain, swelling, and edema in the left ankle; slight fever till twenty-fourth day; swelling disappeared and patient walked on the forty-eighth day.

A healthy girl of 24 experienced a normal labor. Nothing of note occurred till the twelfth day following the delivery. At this time she complained of pain in the left calf. A hot water bottle was applied which gave temporary relief. The next day the limb was still painful and the swelling had increased. There was some discoloration of the leg. I saw the patient on the fourteenth day following the labor. At this time the leg was moderately swollen, was firm, edematous, and tender. The thigh appeared normal. The internal saphenous vein was not indurated, swollen or tender. The temperature was 100° F., and the pulse-rate 88. The remainder of the examination was negative, excepting for the presence of evidences of an old cicatrix in the right pulmonary apex.

I suggested the possibility of pulmonary embolism in this case. The family was much alarmed on hearing this, especially when there was no method to be advised to prevent the occurrence of this serious complication. After the third week the temperature became normal and the swelling gradually disappeared from the leg. On the forty-eighth day following labor the patient was allowed to get out of bed. The limb was slightly swollen, but was useful, and was not tender.

CASE III.—Multipara; normal delivery; curetment on seventh day; right leg affected on sixteenth day; sudden death on twenty-fifth day.

Mrs. H., aged 38, experienced a normal and easy delivery. She was attended by a midwife. On the fourth day she had a chill; the abdomen became distended and tender, and she thought she had fever. On the seventh day a physician curetted her uterus and washed it out with mercuric chlorid solution. She seemed much better till the sixteenth day. At this time she experienced a sudden pain in the right calf. The next day the leg was swollen, tender, painful, and cyanosed. On the twentieth day she was moved a distance of 17 miles on a stretcher. Examination on the twenty-first day, was as follows: Patient rather obese. The right leg was swollen, edematous, painful, and tender. The thigh appeared normal, and the internal saphenous vein was not tender or indurated. Vaginal exam-

ination revealed practically a normal condition. Examination of the abdomen and lungs was negative. The heart was slightly enlarged transversely. A systolic murmur was heard at the apex and in the left axilla. The temperature was 101° F., and the pulse-rate 108 per minute. The patient's local and general condition seemed to improve till the twenty-fifth day, when she suddenly complained of dyspnea, became slightly cyanotic, and died.

Phlegmasia alba dolens, beginning in the ankle and leg, instead of at the groin, is mentioned by most textbooks on the subject. Welch states that the pain is "often first noted, and may remain localized in the calf." He gives further recognition of the ascending variety of milkleg in the following statement: "The cardinal symptom, edema, sometimes ascending, sometimes descending, gives rise to the firm, painful swelling—"

Lusk divides these cases into 2 classes: Primary and secondary thromboses. He says: "In primary thrombosis the swelling usually begins at the ankle, and spreads rapidly to the knee and upward to the inguinal region; in secondary thrombosis, extending from the uterine sinuses, and in the superficial form of phlegmasia, the swelling, on the contrary, travels commonly in the reverse direction, viz., from the inguinal fold to the ankle."

It was my intention, in reading up this subject, to determine the relative frequency of occurrence of the ascending, or peripheral form of phlegmasia alba dolens, and to show the percentage of cases in which death followed. I am unable to find anything in the literature that is of value on these points. My personal experience would lead me to believe that the ascending form of milkleg rarely occurs; but when present is much more apt to be followed by pulmonary embolism and death than is the secondary, or descending, form of the condition: I have seen many cases of descending phlegmasia alba dolens, and have examined many patients who gave a history of having suffered from this affection, but have never known of a case of fatal pulmonary embolism to occur. On the other hand, the 3 cases, herewith reported, are the only cases of ascending phlegmasia alba dolens that I have observed. My experience may be accidental, or it may be that the ascending form of milkleg is likely to be followed by serious complications. The literature, on the subject, is of no value in arriving at a decision.

The symptoms of the 3 cases reported present nothing unusual. The abnormally high pulse-rate in proportion to the temperature stated by Mohler, Wyder and Singer to be characteristic of phlegmasia alba dolens, was not sufficiently marked, in these cases, to be of diagnostic value.

RAYNAUD'S DISEASE.¹

BY

DAVID G. PEYTON, M.D.,

of Jeffersonville, Ind.

Raynaud's disease was first described by Sir Benjamin Brodie, in 1837, but not until 1862 was it given its proper place in medical nosology by Maurice Raynaud, who described it as a separate entity, calling it symmetric gangrene of the extremities.

It is distinctly a disease of early life, usually occurring between the ages of 18 and 35, and more often in women than men. Examples of gangrene due to endarteritis, embolism, or multiple neuritis, and senile gangrene have been reported as manifestations of Raynaud's disease, and only serve to obscure the strict limitations of the disease, which should be confined to that condition presenting local syncope, local asphyxia, and local gangrene only. Gangrene simulating Raynaud's disease occurring in persons over 50, or in those who are subjects of nephritis, syphilis, alcoholism, or diabetes mellitus, should cause one to suspect endarteritis or multiple neuritis. Gangrene of the extremities also occurs in leprosy, diabetes, syringomyelia, and endarteritis obliterans, but the peculiar characteristic symptoms of each should enable us to distinguish them from Raynaud's disease. However, it would seem from reports that many cases of senile gangrene, as well as other things presenting nutritional disturbances, are often classed under this term. It would seem, in view of the fact that Raynaud's disease is almost always a disease of the young, that we should be able to eliminate senile gangrene. Again, chilblains and angioneurotic edema are sometimes mistaken for the disease. I say, chilblains are sometimes mistaken for Raynaud's disease, for I do not agree with Osler in his statement that "Chilblains are the mildest grade of the stage of asphyxia." I am convinced from my own observation, as well as that of others, that the condition involves organs and tissues other than the extremities.

Local asphyxia differs from local syncope, as illustrated in "dead fingers," by being due to fullness of the small veins; in both, the arteries are more or less affected, being thrown into spasms, but in asphyxia the closure of the lumen is less complete.

The etiology is obscure and complex, due in part to the fact that a number of somewhat widely differing conditions have been confounded under this name. The question in causation that first presents itself for our consideration would be, is it truly and strictly a vasomotor neurosis, dependent upon an exaggeration of the excitomotor powers of the central system, or is it due to certain unknown changes in the trophic nerves? The question arises here as to whether or not we have a distinct anatomic set of trophic nerves, or whether all

nerves, in addition to their functions, exercise a trophic influence. I am of the belief that we do have such a special set of trophic nerves, and the fact is evidenced by the following physiologic phenomena:

In the case of the fifth nerve, we have certain trophic changes in the eye—a slow inflammatory process, which may lead not only to destruction of the cornea but of the entire eyeball. On the other hand, we may have greatly increased vascularity, due to disturbed vasomotor changes which do not lead to the disorders of nutrition mentioned. If both vagi are divided, we have death resulting from a condition known as vagus pneumonia, in which gangrene of the lung substance is a marked characteristic. Here the predisposing cause is the division of the trophic fibers in the pneumogastric nerves; the exciting cause being the entrance of particles of food, etc., into the air passages, which on account of loss of sensation are not expelled. Again we have certain bed-sores, due to long confinement in bed and bad nursing, but another class is due to paralysis from disease of the spinal cord, and comes on suddenly. While the foregoing would seem to prove the positive existence of a separate trophic nerve, yet I am not prepared to say that the conditions met in Raynaud's disease are due to a disturbance of these trophic fibers, but desire only to suggest such a possibility.

On the other hand, practically all authorities are agreed that these conditions are due to vasomotor influences. The disease usually comes on in cold weather, and cold seems to be an exciting cause. The visible contraction of the central retinal artery seems further to support the theory of vasoconstrictor spasm, probably originating in the gray centers of the spinal cord.

In intensity we have the three grades, local syncope, local asphyxia, and local gangrene. Leaving the first stage, or stage of syncope, or dead fingers, it is the purpose of this paper to deal more especially with the conditions of asphyxia and gangrene, the former only in so far as it applies to or bears on the case in mind.

The fingers and toes, tip of nose and lobes of the ears are the most likely points of attack. Elsberg reports a fatal case, due to syphilitic origin. Marsh reports a case in a boy of 12, who was hereditarily syphilitic. He was cured, but lost his toes.

Pospelor points out a new sign of this disease—onychophagy—which accompanies it, and which he holds is characteristic, a veritable cutaneous neurosis, analogous to the trichotillomania of Hallopeau. Hutchison holds we are all subjects of Raynaud's phenomena in a greater or less degree, being liable to coldness of the extremities, not only through exposure, but also through nervous influences.

Thompson reports a case of a male, aged 29, of neurasthenic family, who had always been weak and nervous, occasionally having convulsions, and who had been a sufferer for 9 years from Graves' disease.

Our knowledge of the pathology of this extremely rare affection is little more satisfactory than our knowledge of its etiology. However, we have 3 principal theories as to its pathology: (1) Endarteritis obliterans; (2) peripheral spasm; (3) vascular spasm.

The intermittent character of Raynaud's disease is quite sufficient to disprove the endarteritis obliterans theory, which is progressively increasing in its nature. Just what changes, if any, take place in the trophic nerves is unknown, and the suggestion of Raynaud, that of arterial spasm, followed by relaxation and venous engorgement, and consequent pressure, is probably correct.

The local syncope is supposed to be due to vasoconstriction, followed in the next stage by vasomotor paralysis. From this, it would seem the resulting gangrene is due to the pressure and probably not to any trophic changes, such as we have in syringomyelia and other diseases. It is certain the tissue changes are not confined to the soft parts, but affect the bone as well.

¹ Read before the Indiana State Medical Society, at Richmond, June, 1903.

The third stage is reached in few cases only, and then the parts remain asphyxiated, and the gangrene comes on. The blebs and discoloration of parts appear. Other associate symptoms are scleroderma and edema—at other times cerebral symptoms, as torpor and partial loss of consciousness, epilepsy, mania, delusions, and temporary hemiplegia.

I will now present a case illustrating Raynaud's disease.

CASE.—C. E. C., aged 33, a farmer by occupation, was born of tuberculous parents. His father died at the age of 35, of tuberculous peritonitis, and his mother at the age of 48, of pulmonary tuberculosis. Two sisters died of pulmonary tuberculosis, one at 28 and the other at 24. One brother, aged 35, is living and in good health. One sister, aged 37, is living and in good health. The patient knows nothing of his grandparents. He has lived on a farm all his life until May 3, 1898, when he entered the United States Army as a cavalryman, and served until June 23, 1899, when he was mustered out.

He had the ordinary diseases of childhood, malaria when about 10, and grip when 23. He has been a rather extensive user of tobacco since the age of 11, and has drunk to excess for the past 12 or 15 years—at times drinking pure alcohol. He was apparently healthy until the autumn of 1898, while in the United States Army and stationed in Florida, he had severe pain in back, full length of spine, and shortly afterward his hands and feet became edematous, and blebs filled with a bloody serum made their appearance, extending on the hands to the wrists, and on feet and legs above the knees. There was apparently no fever (so patient states), and the attack lasted about 3 weeks, when the entire cuticle of both hands and feet was shed *en masse*. The attack left the joints of both hands stiff. After this he was again apparently well, until the fall of 1900, when he had a recurrence of the trouble, and was treated in a hospital in Indianapolis, with the same general symptoms. He recovered from this attack in about 3 or 4 weeks, but in this attack he not only lost the skin of both hands and feet, but the finger nails of both hands came off. His third and last attack came on him at his home in the country on February 15, 1903. He had been engaged in gathering corn the day before, and was exposed to the cold. On the following day, the hands and feet presented the same class of symptoms as before. On March 9, I examined the patient for the first time and found all the fingers and thumbs of both hands thoroughly gangrenous, with perfect lines of demarcation formed just below the metacarpophalangeal articulation in the fingers, while in the thumbs, the line was near the middle. Amputation was decided upon and in both hands the evidence of nutritional disturbance was most marked, the soft parts breaking down under the least effort. The bones were soft and spongy. The amputations were completed without the use of Esmarch's bandage or anything to control the hemorrhage, all the fingers of one hand being removed before the flaps were closed. In neither hand was there any hemorrhage. His chart while in the hospital showed nothing of special importance, his temperature never exceeding 101°, and that only for a short time. During the first week following amputation, his temperature ranged from 99° to 101° at the end of which time it became normal and remained so.

Union of the stumps of the right hand was by first intention, but the left hand refused persistently to heal, and even at this writing, is not perfectly healed. One condition especially existed for some 3 weeks following the operation, and that was the tendency to a return of the asphyxiated condition of both hands, and the line would form just above the wrists on both hands. The treatment consisted of frequently douching the hands and arms with hot normal saline solution, and the alternate hot and cold douche along the entire course of the spine and later of the static electricity in the wave current and static spark.

I do not believe that any good is to be gained by any internal medication, as every drug heretofore suggested, was tried in the case with no apparent result.

December 24, 1903. The patient entirely recovered and has been perfectly well for about five months.

Smallpox and Finsen Red Light.—Baer reports 18 cases of smallpox occurring in Strasburg. With the exception of 1 patient, who had been vaccinated successfully 5 years before, and another 7 years before, none had been vaccinated within 12 years; the gravest cases not in 39 years, 40 years, and 46 years. Of the 18, 9 were light cases; of the other 9, 6 were treated by the author according to Finsen's red light theory. The chemically acting rays of daylight were excluded by means of red curtains; in none of them did the vesicles suppurate, thus preventing the secondary stage of suppuration with its grave symptoms. The duration of the disease was very much shortened. They all had glandular enlargement and albuminuria. The scarring danger was reduced to a minimum in all the cases. To produce these good results it is, however, necessary to exclude all daylight during the entire disease.

BRADYCARDIA, WITH REPORT OF AN UNUSUAL CASE.¹

BY

J. WILLIAM WATSON, A.M., M.D.,
of West Hartford, Vt.

It is well known that physiologic slowness of the pulse occurs in the puerperal state, repose, fasting, and old age, and that it is found habitually in certain people running from 40 to 60. For example, Napoleon, is reported to have had a pulse of only 40, which undoubtedly was a family trait, as a slow pulse may be inherited. These cases in which even after death no appreciable lesion is found, are cases of "essential bradycardia."

Butler designates that we rarely find a pulse regularly below 40, concomitant with health, but cases are on record showing the pulse to have sunk below 20 down to 8 or 9, and even as low as 4 beats per minute. All such cases are no doubt pathologic, and this is where the proper study of bradycardia comes in, although even here a doubt may arise. For instance, in a man, about 80, with the sclerosed arteries which are apt to occur at that age, and with occasional symptoms of Stokes-Adams' syndrome, brought on probably by excitement or overexertion, the pulse which had previously been nearly normal, may suddenly drop below 30, and remain regularly there for nearly 6 months. In a case like this it would appear that the organism is trying to adjust itself to a new order. Therefore, can it properly be called pathologic? I desire to report an interesting case in which such conditions were present.

The patient was a man prominent in mercantile affairs, and had always led a very active life. Two years ago he had some gastric trouble, but at the present time, aside from a habitual cough, supposed by some to be due to fibroid tuberculosis, he seemed in a fairly good physical condition for a man of 78. His pulse was normally 66. I was called to see the patient, and found him in a very alarming syncope, apoplectic form or epileptiform condition; pulse was 18, and he presented every symptom of Stokes-Adams' disease. I was told he had 2 previous attacks; the first occurred 2 years previous, while the patient was running a horse-rake in the hay-field. He fell under the horse and was picked up unconscious. The condition of the pulse at that time is not known, as he was not attended by a physician. The second attack, which only lasted a few minutes, occurred a week ago. The third attack, for which I was called, was more severe than the others, and occurred one Saturday night after his return home from an unusually hard day at his place of business. He responded promptly to stimulation, but his pulse would not go above 24. He was put to bed, but soon insisted on going up stairs to his own room, which he did almost unassisted. He passed a comfortable night, but his pulse still remained low even though cardiac stimulants were used continuously. His fourth and most severe attack occurred 18 hours later. I was hastily called, and found him in an apparently dying condition with a pulse down to 16. He responded, however, to the same treatment of the previous evening, and soon laughed at our fears, and told us that he was a hard man to kill. He was closely watched night and day for a month, and the attacks grew less and less severe, and only occurred at long intervals. At no time during the month did his pulse go over 32, and usually it remained at 26 or 24. He was now allowed to leave his bed. He did not seem to suffer any bad effects in the upright position, even though the bradycardia was excessive. However, he was repeatedly cautioned against overexertion, and was told that he must have absolute rest, and under no circumstances go back to his place of business. These cautions were of no avail, for he was soon spending a few hours daily at his office and store, and now and then taking a ride in his carriage. Often these rides were taken alone. Occasionally he was seen socially by me, and would permit his pulse to be counted. At no time did I find it over or even up to 30, and it was usually 24. The only inconvenience that he complained of was that he felt faint on exertion, and that he tired easily. He was again cautioned against overexertion, and was advised to continue taking a cardiac tonic, to which he replied that he had not much use for medicines or doctors.

He continued in this condition about 3 months, with pulse regular and slow. His system seemed to be properly adjusting itself to this new order. Up to this time his death had been expected at any moment, but now it appeared as though he might live indefinitely (so far as his pulse was concerned) with this acquired physiologic bradycardia. Aside from arterio-

¹ Written especially for *American Medicine*, but the first draft was read in a discussion on tachycardia before the joint meeting of the White River Medical Association and Windsor County Medical Society, held at White River Junction, Vt., December 8, 1903.

sclerosis, no trouble of his circulatory system was discovered. On auscultation of the heart only the classic sounds were heard, but so far apart (2 to 3 seconds between beats) as to make one feel that it had almost stopped.

One evening he heard a noise in his stable, and contrary to his physician's orders, went out to investigate. He did not return as soon as was expected, and as everything seemed quiet in the stable, a search was made and he was found behind one of the horses in a syncope condition. He soon revived and complained of no unpleasant sensation aside from faintness. This spell had undoubtedly been brought on by the excitement and some probable exertion in controlling the horses. Treatment consisted of the administration of glonoin .2 mg. ($\frac{1}{200}$ gr.) in solution every 5 minutes and inhalations of strong ammonia.

During the next 2 months he continued to superintend his business and rode considerably (generally alone) to oversee the work on the farms he was interested in. While in a hay-field, but doing no manual labor, another attack occurred. He recovered promptly on being vigorously fanned. In speaking of the event, he told me that he was much perturbed over the way hired help worked now-a-days. They did not try to see how much work they could do for their employer, but they did try to see how much time they could get in on him. This mental perturbation was evidently the cause of this attack. Anything that tended to unbalance his circulation seemed likely to produce an attack. As a rule, his family had no trouble in bringing him out of them, so a physician was not called in after the first month or 6 weeks.

During the first few days of the sixth month after his first attack he did not feel so strong as usual, so he remained quietly at home. On the fourteenth day of this month he had a "bad spell" in the morning, but recovered with the usual family treatment. In the afternoon of the same day he had another attack, and not recovering so promptly as heretofore, the physician was quickly summoned. His pulse was down to 18, only beating 3 times in 10 seconds. He was cyanotic and was having epileptiform convulsions. His condition was very much the same as when first seen nearly 6 months previous. The same treatment was followed, consisting of the administration of strychnin, nitroglycerin, and digitalin subcutaneously, aromatic spirits of ammonia by mouth, and strong ammonia inhalations. Much to our surprise his pulse went bounding up to 60 and 66 as in health, but his breathing did not improve as heretofore. Artificial respiration was tried, but was of no avail. The pulse gradually dropped down to 18, where it lingered for a few moments, and finally, while the patient continued to breathe slightly, it stopped altogether, but all the time it had been strong. This rise of the pulse from 18 to 66 and then the change back to the 18 and below, seemed to produce a severe shock to the system, from which it could not recover. At any rate, the patient died within 15 minutes after the arrival of medical aid. There was no necropsy.

This case gives a chance for much speculation. Another physician and myself think it possible that the patient might have lived could he have been subjected to a rigid Weir Mitchell course. Probably in this way the Stokes-Adams' syndrome could have been avoided. According to Osler, his old age and arteriosclerosis would account for these unpleasant symptoms, which were usually brought on by overexertion or mental excitement. The fact that the patient lived comfortably so long (5 months and 14 days) with such a low pulse seems to indicate that it was becoming physiologic and that his arteriosclerosis was concomitant with his old age and not otherwise necessarily pathologic in producing or being a part of the Stokes-Adams' syndrome. Butler says that these symptoms may occur from time to time when the bradycardia is excessive (20 to 30), which condition existed in this case.

To me this does not appear to be a case of true Stokes-Adams' disease. By some unaccountable cause the pulse was lowered and the economy made a strong fight to adjust itself to the new arrangement. At all events, it appears that this low and continued regular pulse must have had some symptomatic etiology, occurring, as it did, in an active man and one of exceptionally good habits, whose pulse had ranged heretofore between 60 and 70. In reviewing the case, it appears to me that the rest treatment after the first 6 weeks was more efficacious than drugs. For the condition of slow pulse, Osler says that little can be done. He also adds, that a great majority of the cases are not dangerous.

In closing this paper I wish to thank the neighboring physician for the early notes in this case. Of late years considerable interest has been aroused in bradycardia, and this paper has been written to place on record a very interesting, if perchance, not a very rare case.

THE WORLD'S LATEST LITERATURE

Journal of the American Medical Association.

March 19, 1904. [Vol. XLII, No. 12.]

1. The Treatment of Lobar Pneumonia. W. GILMAN THOMPSON.
2. Tumors Involving the Cauda Equina: With Report of Case. GEORGE GILBERT DAVIS.
3. Recent Advances in Actinotherapy. WILLIAM S. GOTTHEIL.
4. Examination of the Blood of Pneumonia Patients for Pneumococci. FRANK C. KINSEY.
5. The Use of Silver Foil to Prevent Adhesions in Brain Surgery. M. L. HARRIS.
6. A Method of Dispensing with Rubber Gloves and the Adhesive Rubber Dam: A Preliminary Note. JOHN B. MURPHY.
7. Simultaneous Extruterine and Intrauterine Pregnancy: Report of a Case. CHARLES A. STILLWAGEN.

1.—Treatment of Lobar Pneumonia.—W. G. Thompson endeavors to emphasize what has seemed most satisfactory to him in his individual work. Good nursing and watchfulness outweigh polypharmacy and specifics. He notes specially the importance of not crowding an over-taxed heart with too much stimulation and of selecting the stimulant according to the balance between vascular tone and the effort the heart is already making; the uselessness of the so-called specifics for pneumonia, and as a rule of expectorants; the importance of prevention of indigestion, and particularly of tympanites; the great value of hypodermoclysis in certain cases; the uselessness of topical applications except in relieving pleuritic pain; the necessity of prescribing proper intervals of rest free from incessant efforts at medication. [H.M.]

2.—Tumors Involving the Cauda Equina.—G. G. Davis notes that these tumors originate in the nerve-trunks or the meninges, or in the structures outside, especially in the vertebral column. Those in the nerve-trunks are not numerous, those from the meninges less common and the tumors are small. The greater number are extradural producing symptoms by pressure and infiltration. The majority are sarcomas generally of the small-celled variety and very malignant. Differential diagnosis from disease of the conus medullaris is important as the latter is not amenable to surgical treatment. It is proper to assume that the upper limit of the caudal lesion is just above the exit of the highest nerve disturbed. In the writer's case reported in detail this was the fourth lumbar, the growth being sarcoma, removed by operation, but without relief of symptoms. [H.M.]

3.—Actinotherapy.—W. S. Gottheil limits the term to the method using only the violet and ultraviolet rays, phototherapy including all kinds of light treatment. It practically includes treatment only with concentrated sunlight and the various forms of the electric arc, not incandescent bulbs, the latter having little actinic power and penetration. The rays employed are bactericidal and capillary dilation is invariable, a distinct endovasculitis resulting after a time, followed by atrophy. There are remoter effects in the stimulation of oxidation and connective-tissue formation. The tissue changes are moderate and controllable; rapidly brought about, and without remote effects. It is the most effective treatment in lupus vulgaris, tuberculosis verrucosa cutis, tuberculous ulcer, postmortem tubercle, etc. The cicatrix is often hardly apparent. Lupus erythematosus is a new field with an encouraging showing. Results in alopecia areata have been satisfactory, as also in birthmarks, carcinoma, epithelioma, rodent ulcer, Paget's disease, acne rosacea, and parasitic skin diseases. It has been recommended in hay fever and pulmonary tuberculosis. [H.M.]

4.—Examination of the Blood for Pneumococci.—F. C. Kinsey began the investigation with 4 questions: 1. Can pneumococci be found at any time in pneumonia? The results answer this in the affirmative. 2. With what frequency may they be found in all cases? In the first series there were 3 positives in 25 patients, or 12%. In the second series, with a method more favorable to the growth of the organism, there were 19 cases, or 76%. Of 6 negative cases, 2 were unfavorable for recovery of the pneumococcus from the blood on account of the condition of the patient at the time of examination. One was negative with a temperature of 99.6° during a pseudocrisis, and the other was negative with a temperature of 99.8° after a crisis the previous day. Had an examination been made during high temperature, the pneumococcus might possibly have

been isolated. On the other hand, 2 cases were positive with subnormal temperature. In the other 4 negative cases no explanation can be offered. From the results it is probable the pneumococcus may be found in every pneumonia patient, negative results being due to unfavorable conditions for growth or failure in technic. 3. What is the simplest method of finding them? Take from 3 cc. to 6 cc. of blood, with a dilution of over 1 to 12 of a liquid culture medium, preferably bouillon. 4. What is the prognostic value of the results? Of 19 positive cases, 69% recovered and 31% died. Of negative cases, 33% recovered and 67% died. Hence no worse prognosis attaches to positive than negative findings. [H.M.]

5.—Silver Foil to Prevent Adhesions in Brain Surgery.

—M. L. Harris discusses the failure of operation to relieve symptoms permanently in many cases owing to the subsequent formation of adhesions and also the employment of different methods and materials to prevent this with their disadvantages. Whether organic substances such as egg membrane, prepared ox peritoneum, etc., will prove of value remains to be determined. Thin rubber has been used with good results, but tends to roll up after insertion; it may also be disintegrated by granulations. Heavy plates may tilt and act as irritants or work their way to the surface, or suppuration may occur necessitating their removal. The author believes thin foils are the best and of these he prefers silver because so thin and soft and smooth, conforming to all irregularities of the surface. As many layers may be applied as necessary to secure an unbroken surface. It exerts a beneficial influence on healing surfaces. [H.M.]

6.—A Method of Dispensing with Gloves and Rubber Dam.

—J. B. Murphy has succeeded in finding an application which practically seals skin surfaces, preventing the escape or admission of secretions, and yet does not interfere with the sense of touch or impair the pliability of the skin. This is a 4%, 6% or 8% solution of gutta-percha in benzine or acetone. The benzine solution wears the better. For the abdomen the acetone solution has the advantage of drying in 3 or 4 seconds, while it takes the benzine solution from 2 to 3½ minutes. The acetone coating is only slightly adhesive, while the benzine coating is sticky. The coating may be renewed between operations if it wears off the tips of the fingers. The coating will resist soap and water and is removed by washing in benzine. The solutions must be made in sterile menstrua and do not stand subsequent boiling. The skin is soft and smooth after removal. [H.M.]

7.—Simultaneous Extrauterine and Intrauterine Pregnancy.

—C. A. Stillwagen reports a case. That fecundation is practically simultaneous in the majority of cases is borne out by unimpeachable reports. It is the phenomenon of a twin pregnancy with one ovum arrested in its course. No pathologic condition can be specially charged with its occurrence, except those which obtain in ordinary cases. It is looked on as a rare condition, but no doubt many cases occur which are overlooked. The extrauterine pregnancy may terminate without attracting enough attention to make a diagnosis, while the intrauterine pregnancy continues to term or aborts; or death may occur from rupture of the sac and the intrauterine pregnancy remain undiscovered. Sometimes abortion is mistaken for expulsion of the decidua. Sometimes the intrauterine gestation may be destroyed by curetment. In order to save the intrauterine fetus, early diagnosis and removal of the pregnant tube is most important. [H.M.]

1. The Relation of Some Special Causes to the Development of Neurasthenia. ROBERT T. EDES.
2. The Intraabdominal Rupture of Ovarian Cysts, with Report of a Case. ERNEST BOYEN YOUNG.

1.—The Relation of Some Special Causes to the Development of Neurasthenia.—R. T. Edes defines neurasthenia as a paresis of the attention and will, the result of long-continued overfatigue, which in its turn is the consequence of enforced and often unsuccessful overaction of some motor activity carried on under emotional stress. He enumerates some of the

special causes considered by other writers as potent and comprehensive, including overwork and worry, lithemia, eyestrain from ametropia or from muscle imbalance, sexual diseases and abuses of the sexual organs, and abnormal sexual feeling, ovarian irritation, and enteroptosis. The psychic, not the muscular effort, is the important factor in fatigue. The exhaustion from monotony comes from fatigue of the will in forcing one's self to keep on in spite of want of interest, disgust and ennui. He points out the relation of emotional stress to the break downs attributed to overwork in teachers of physical culture, in school children, college students and business men. He believes that sexual overexercise and suppression have been exaggerated as sole determining causes of neurasthenia, and that while neurasthenia may be much benefited by local treatment of pelvic diseases, local lesions are much aggravated by nervous and general debility. He discusses the vicious circle formed by neurasthenia and dyspepsia and the lack of intimate connection with enteroptosis and floating kidney, and the absence of fixed relation between headaches and excess or diminution of uric acid. He points out the relation of imperfectly functioning eyes to psychic strain under feelings of failure and disappointment during ambitious attempts at overuse. He thinks that the continued use of any muscle at a high grade of tension and attention may possibly cause headache, refers to the fatigue from excessive effort to hear distinctly, and cites a case of neurasthenia in which headaches were brought on by reading raised type with the fingers. [H.M.]

2.—Intraabdominal Rupture of Ovarian Cysts.—E. B.

Young reports a case seen in the Boston City Hospital, occurring in an unmarried woman, aged 42. The abdomen was distended by a hard, symmetric tumor rising from the pelvis and extending to the umbilicus. Her poor physical condition delayed operation and on the fifth day vomiting began, pulse was poor, and collapse supervened. She complained of abdominal discomfort and showed signs of free abdominal fluid with a diminution in the size of the cyst. She died the next morning and at the autopsy a great quantity of yellowish fluid containing leukocytes flowed out. The omentum was firmly adherent to the abdominal wall and to the intestines. The lower half of the abdomen was filled with a multilocular tumor with many adhesions. The etiologic factors in rupture may be predisposing causes, such as thin friable walls, rapid rise of internal pressure and formation of firm adhesions, changes in cyst walls which occur especially in papillary cystomas, and trauma, either internal or external. The symptoms of rupture are a sensation of something giving way and the outpouring of fluid into the abdomen, pain, tenderness of the abdomen, collapse, nausea and vomiting, fever, disappearance of tumor and change in form of the abdomen, free fluid in the abdomen, palpation of the remains of the tumor, increased urinary secretion, tendency to sweat, loss of friction of tumor upon abdominal wall, presence of peptones in the urine. As to treatment, Young considers operation indicated in every case in which surroundings will permit. [W.K.]

Medical Record.

March 19, 1904. [Vol. 65, No. 12.]

1. A New Treatment for Fracture of the Neck of the Femur. ROYAL WHITMAN.
2. The Soluble Ferments of Cow's Milk. JOSEPH LESPERANCE.
3. Some Operative Methods for the Fixation of Movable Kidney and their Result. ALEX. B. JOHNSON.
4. Asthenopia and Headache from Eyestrain. JAMES R. NELSON.
5. Dilation of the Bladder in Suprapubic Cystotomy. E. BLASUCCI.
6. Gastroenterostomy for Carcinoma of the Stomach. W. P. MCINTOSH.
7. Primary Pyelitis in Infants. MARCELL HARTWIG.

1.—Treatment of Fracture of the Femoral Neck.—

Royal Whitman asserts that such fractures, even among children and adults in middle life, are more frequent than is commonly supposed. Many instances are unrecognized because the fracture is not complete. In Hamilton's series of cases, treated at the Bellevue Hospital, 37% were more than 60, and 40% were less than 50 years of age. In Scudder's 16 cases, 7 were between 40 and 50, and but 3 were over 60. Whitman believes that our method of treating these cases accounts for the deformity, pain and impaired function almost universal after

such treatment. Whether the fracture be complete or incomplete the tendency of the iliopsoas, gluteus maximus and other detached muscles is to produce an upward displacement of the great trochanter, and if union does not occur there is deformity, limited abduction and impaired function. The method of treatment suggested by him is that the leg should be placed in abduction and held so in a plaster cast. In fact, the position of the leg with the means of retaining it is very similar to that employed by Lorenz in his method of treating congenital dislocation of the hip. Whitman says that this treatment is especially indicated whether the fracture be complete or incomplete in childhood and at any time up to old age, and his belief is that it could be employed with advantage even among elderly people. A few cases which he has so treated in childhood have recovered most satisfactorily, while in 2 cases which he has treated recently among elderly people sufficient time has not elapsed to be sure of the result. [A.B.C.]

2.—Soluble Ferments of Cow's Milk.—J. Lesperance refers to animal experimentation, showing that artificial mixtures of albumins, fats and sugars in the same proportion as in milk will not sustain life beyond a limited period, the enzymes being absent from the fluid used. This explains why sterilized foods have not fulfilled expectations. Seeds will not grow in sterilized earth on account of the absence of bacterial secretions. The breathing of sterilized air is disastrous to animals. The ferments of milk originate both in the organic and the bacterial cell. The writer traces the steps that led to the discovery of these and the differentiation of one from another. Those that have been definitely determined are trypsin, pepsin, the lipase and oxidizing ferments, and a glycolytic ferment. [H.M.]

3.—Fixation of Movable Kidney.—Alex. B. Johnson reviewed the literature of this subject. More than a score of different methods is described rather briefly, and some statistics given as to the result. The author has had the rare opportunity of examining several kidneys *in situ* that had previously been operated upon by the Riedel method, in which the fibrous capsule is incised along the convex border of the kidney, separated for a moderate distance on either side of the incision over the parenchyma and sutured to the muscular sutures on either side of the wound. In each instance the kidney was found very firmly fixed in its new position. He believes, after an observation of some 20 cases operated upon by this method, that so far as fixation of the kidney is concerned, and freedom from the risk in operation, the method leaves little to be desired. The methods employed by Senn, Jacobson, Edebohl, Tuffier, Morris, and others are commended. Henry Morris uses an oblique lumbar incision, removes a portion of the fatty capsule about the kidney, and passes 3 sutures deeply into the posterior surface of the organ, one near each pole, and one midway. Each suture is buried 2 cm. ($\frac{1}{2}$ in.) within the renal substance, and penetrates 1 cm. ($\frac{1}{2}$ in.) into the thickness of the organ; the upper suture passes through the fatty capsule, the transversalis fascia, and the deep muscles. The lower suture is similarly passed, while the middle suture is passed through both edges of the wound, including the fascia and muscles. The 57 cases operated upon by this method, as reported by Morris, resulted in 57 cures. [A.B.C.]

4.—Asthenopia and Headache from Eyestrain.—J. R. Nelson divides headaches into toxic and reflex. Eyestrain acts reflexly, and through lowering nervous energy invites toxic conditions, especially in the digestive tract. He discusses the mechanism and symptoms of eyestrain. It is the province of the oculist not only to make out the refractive error and give proper glasses, but to give or suggest proper treatment for the morbid conditions disclosed by his examination. It is as rational for the general physician to send his eyestrain patients to an optician as to send his fracture cases to a manufacturer of splints, etc. [H.M.]

5.—Dilation of the Bladder in Suprapubic Cystotomy.—E. Blasucci recites some of the dangers in dilating the bladder previous to a suprapubic cystotomy and states there are cases in which distention cannot be practised. These are operations on the female, fistulous bladder, fracture of the urethra and rupture of the bladder by trauma, and stone impacted in the prostatic urethra. An injection of 200 cc. to 250

cc. ($\frac{1}{2}$ oz. to 8 oz.) of liquid under complete anesthesia in an adult is harmless; in many instances much more may be injected. An injection of 200 cc. raised the peritoneal culdesac about 1 cm. ($\frac{1}{2}$ in.) above the pubis, whereas with an empty bladder this culdesac is $\frac{1}{2}$ cm. (1 in.) below the pubis. Injections postmortem and antemortem give different results, on account of the physiologic resiliency of the bladder. His conclusions are: 1. A careful injection is of no danger to the bladder. 2. A limited dilation of the bladder is preferable to none. 3. Anatomic researches in regard to the ascent of the peritoneal fold are of little or no value for the surgeon, and in practice we find more working space than by these researches, we should suppose. 4. There are practically no cases in which suprapubic cystotomy is indicated, in which dilation of the bladder cannot be carried out. [A.B.C.]

6.—Gastroenterostomy for Cancer of the Stomach.—W. P. McIntosh reports the case. A man of 43 gave the history and symptoms which led to a diagnosis of cancer of the pylorus. Laparotomy was performed with the hope that pylorotomy could be done. The extent of the disease prevented such an operation, and posterior gastroenterostomy was performed, the jejunum, about 20 inches below the pylorus, being anchored to the posterior wall of the stomach by means of a Murphy button. The patient made a good recovery and lived in comfort for 3 months after the operation without having passed the button. A postmortem examination showed the button had remained in the stomach. At death the pyloric opening was almost completely closed and the mesenteric glands were enlarged. [A.B.C.]

7.—Primary Pyelitis in Infants.—Marcell Hartwig has seen few cases reported in the literature. He has had 4 such cases under his care within the past 2 years. The symptoms very much resemble those of typhoid fever in the infant; nothing points especially to any urinary trouble, and in one instance he happened upon the diagnosis after a negative Widal test was made. Examination of the urine showed the fluid to contain all of the characteristic microscopic elements of pyelitis. The duration of these cases is generally several weeks; the best results are obtained by the use of turpentine, urotropin, and other drugs to allay the irritability of the urine. He urges practitioners to be on their guard against this disease when the child has the symptoms of typhoid fever. [A.B.C.]

1.—Intestinal Anastomosis.—H. M. Hepperlen has devised a stitch and new support for the bowel to be used in intestinal anastomosis. He uses a cylinder made of gelatin which serves as a firm support, takes a very short time to introduce, and, when the work is completed, becomes absorbed, leaving no after-trouble. The same material may also be used for gastroenterostomies or gallbladder work, by having it moulded in requisite sizes. When the capsule is placed in position, he inserts a few interrupted sutures through all the coats of the bowel to hold the parts in coaptation. He then completes the work by using a fine intestinal silk, 24 inches long, doubled, with a needle on each end. He starts the first suture under the mesentery attachment, inserting a needle with each hand at the same time through the 2 outside coats of the bowel, an eighth of an inch from the cut margins; he then picks up a loop about a twelfth of an inch in length, according to the method of Lambord, draws the parts together and ties them at each stitch. Continuing thus until he has completely encircled the bowel, he closes the mesentery opening with the same suture. The advantages claimed for this suture are: 1. Its simplicity. 2. It can be introduced practically without handling the parts, in about a fourth to an eighth of the time required for any other stitch. 3. When the bowels are sewed together by this method they are held more firmly than with any other stitch known to the author. [C.A.O.]

3.—Senile Pneumonia.—This article, by S. S. Cohen, is a

clinical lecture, in which the author discusses the subject of senile pneumonia, and illustrates the value of persistence in the application of wellknown principles and wellknown measures under apparently unpromising circumstances. The author says he is but little influenced by statistics in determining upon a line of treatment in a given case. The record of the case discussed shows that from time to time, in accordance with the indications of the particular moment, the drugs used, singly or in combination, were nitroglycerin, digitalis, strychnin, atropin, and alcohol. Previous to this a mixture of ammonium chlorid and ammonium carbonate was used coincidentally with strychnin and whisky. The author says that aged patients needing alcoholic stimulation usually receive better service from champagne. It is less likely to disturb the stomach, and it is usually more readily accepted. Hot flaxseed poultices, well made so as to retain their heat for 4 hours, were kept about the thorax during the day, and at night were replaced by lamb's wool jacket, for the better part of a week. At one time in the course of the case, oxygen was given. The author gives in detail the method of administering oxygen in such cases. In many cases it should be given freely. In a severe case, let it run for an hour, or for 6 or 12 or 48 hours if necessary, removing it only when needed to give the patient rest or sleep, to feed the patient, or to carry out other portions of the treatment. After 2 or 3 hours of continuous administration of oxygen there will usually be sufficient improvement to warrant its intermission for a couple of hours. In milder cases a half hour's use of the oxygen every second or third hour may suffice. [C.A.O.]

4.—Writer's Cramp.—Gustaf Norstrom maintains that a large percentage of cases of writer's cramp is secondary to chronic myositis and that many of them may be cured by massage. He says there are sometimes cases in which no deposits are found in the muscles in spite of the most careful examination and that there are others, although exceptional which cannot be cured by massaging the deposit. He has treated 47 cases. In 34 cases he found muscular inflammations and in 13 he did not find anything. In the majority of cases the patients presented the tremulant form in a more or less pronounced degree. The only treatment applicable in the affection mentioned is massage. This latter must be applied to the muscular inflammations, which are the most frequent cause of the ailment. The manipulations which are necessary are effleurage and proper frictions. Two cases are reported in detail. [C.A.O.]

6.—The new biologic test for human blood, with a report of its employment in a recent murder case, is given in detail by A. Robin. He says, in conclusion, that human blood can be distinguished from that of other animals, except, perhaps, monkeys, by means of antiserum. Antiserum may be obtained by immunizing rabbits' against human blood. For immunization it is most convenient to employ the blood obtained from human placenta. From 6 to 8 injections, 8 cc. to 10 cc. each, should be made at intervals of 3 to 5 days and the serum secured at least a week after the last injection. At the end of the immunization period it is well to test the potency of the antiserum by securing a small quantity of blood from the ear vein or any of the deepseated vessels. To obtain the serum from rabbits for testing purposes, it is not necessary to sacrifice the animal, as sufficient serum can be secured from any of the large veins or arteries, the femoral being the most accessible. Care should be taken to have all solutions perfectly clear and the blood sufficiently dilute. The antiserum should be used pure. Control tests on blood from different domestic animals should invariably be made. With all the precautions observed, a distinct clouding within 30 minutes and a precipitate within 2 hours is certain evidence that the blood is human. In medico-legal cases, the tests should be repeated at least twice, so as to exclude any possible error. [C.A.O.]

8. Forensic Eye Aspect of Tabes. JAMES G. KIERNAN.

1.—Individual Equation in Surgical Operations.—W. L. Estes gives a lengthy discussion with regard to the general condition of the patient in reference to habits, environment, age, sex, physical condition, extent and location of the operation, etc., and holds that it is particularly important to know when *not* to operate. He asserts that preventive surgery is just as possible and just as important as preventive medicine. It is generally conceded by pathologists as well as surgeons that even after a lesion has started there is a period which may be called the precancerous period, during which a tumor which may subsequently be most malignant has the qualities of a benign tumor, and may be removed with assurances that it will not recur. It is of the greatest importance that every tumor shall be removed as soon as it develops. People generally are not thoroughly impressed with the tremendous importance of this fact. Surgeons should endeavor to educate the people to thorough appreciation of this. Cancer may be prevented, at least in some instances. Surgeons first should teach family physicians, and they in turn their families, how to prevent and to stop the progress of cancer. Temporizing in surgery will not do. [A.B.C.]

2.—Valvular Disease of the Heart.—S. S. Burt emphasizes the importance of an ability to discriminate clinically between adequate and inadequate compensation. Ordinary occupations and recreations not too strenuous need not necessarily be abandoned, systematic outdoor exercise, preferably walking, is indispensable. Violent exertion, exciting emotions, and excessive eating and drinking are positively injurious. Temperateness should be the watchword. With failing compensation rest is of paramount importance, and sometimes all that is necessary. Digitalis in this condition and irrespective of the valve affected is the sole remedy that cannot be dispensed with. Large doses may be given for a short time and small doses for a long time or indefinitely. Ruptured compensation is the beginning of the end, however, long deferred by intelligent management. [H.M.]

3.—Pain in the Epigastrium.—F. H. Murdoch notes that pain may be due to hyperacidity, hypersecretion, hyperesthesia, nervous gastralgia, biliary colic, certain affections of the spinal cord, cancer, gastric ulcer, pancreatitis, some forms of appendicitis, and Addison's disease. He discusses briefly the points of differentiation, and reports a few cases. [H.M.]

4.—Significance of Pus and Blood in the Urine.—Richard Douglas first discusses pyuria, and gives various directions as to how to find the seat of suppuration in case pus is found in the urine. If the urine be alkaline, the pus is possibly of bladder origin. Rosenfeld claims that the greatest differentiating point is the quantity of albumin in the urine. If the pus comes from the bladder, the albumin is low—about 1.5%; if from the kidney, 3% or more. After infection, particularly in the use of the catheter in old men and pus from prostatic abscess and suppurating seminal vesicles in young men, the foreign body in the bladder, usually in the form of the calculus is the most frequent cause of vesical pyuria. Renal suppuration inducing pyuria may be recognized by seeing the purulent flow in the bladder when using the cystoscope, and by microscopic examination of urine from each kidney separately. Pyelitis in children is considered at some length, likewise pyonephritis and pyonephrosis. The latter portion of the article is devoted to a consideration of blood in the urine, and is such as is ordinarily found in the textbooks on this subject. The common causes of hemorrhages from the bladder being cystitis, stone, neoplasm, and tuberculous ulceration; while from the kidney they are calculus, traumatism, tumors, tuberculous nephritis, and movable kidney. [A.B.C.]

5.—Neurasthenia.—H. Richardson finds in practically all cases the disease affects those who work with their brains, its rarity in the laboring classes suggesting that want of physical exercise is a factor in its etiology. Headache occurs in 90% of patients, worse in the morning, decreasing as the day advances.

The pain is a dull, numb feeling, occasionally lancinating or causing intense agony. Insomnia is of 2 kinds, profound sleep for several hours followed by restlessness, with numbness, which may be unbearable, and with perhaps sensations of emptiness in the epigastrium and frequent micturition; or there may be uncontrollable desire to sleep, which disappears as soon as the patient lies down, the entire night being spent in short snatches of semiconsciousness. There is vertigo, with empty feeling in the head, weakness of the limbs, a cloud before the eyes, with all objects on the same plane. Sometimes there is agoraphobia. In some cases there are pains in the spinal column. The reflexes may be normal or exaggerated. The digestive functions suggest autointoxication. There is continuous secretion of HCl, with want of motility, therefore feedings should be frequent, but small in amount. The urine is clear and large in amount. Maximum blood-pressure compared with the mean is low, and falls on taking the erect position. Primarily, neurasthenia is due to decreased sensibility or power of the vasomotor system. The genital and mental functions are depressed. Restlessness is often marked and sometimes irritability. It is not the pressure of responsibility but lack of physical exercise which has increased the disease in the life of today. There is no specific treatment. Drugs should be used as little as possible. [H.M.]

6.—The Theatrical Profession as a Factor in the Dissemination of Disease.—S. H. Brown discusses this question at some length, and concludes as follows: 1. That the theatrical profession is a factor of great importance in the dissemination of scabies, pediculosis, syphilis, and gonorrhea, by reason of its peculiar sociologic position. 2. That this influence is greater in traveling troupes than in companies located permanently in the large cities on account of the lack of accommodations and unhygienic conditions under which they live. 3. Living apart from the rest of the world as they do, to a great extent they are deprived of the medical education which is becoming so popular with the rest of the laity. 4. Lack of time prevents the members of this profession from consulting able medical men in the large cities except when physically incapacitated, and in consequence they fall into the hands of unscrupulous and ignorant physicians or charlatans. [A.B.C.]

8.—Forensic Eye Aspects of Tabes.—J. G. Kiernan calls attention to the fact that while neurologists lay stress on the Argyll-Robertson pupil in the differential diagnosis of locomotor ataxia it has been temporarily noted after railroad accidents and other shocks, in cases in which no subsequent evidence of grave neuroses had occurred. Exceptionally it has been found in alcoholism. It occurs early in locomotor ataxia, parietic dementia, and constitutional syphilis. As it is frequently absent in the latter disease it may be an expression of intercurrent toxic states. In the writer's opinion locomotor ataxia due to traumatism does not exist. [H.M.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

Adiposis Dolorosa: Dercum's Disease.—The clinicopathologic entity now known to the medical world as *adiposis dolorosa*, or *Dercum's Disease*, is one of the most notable of the additions made to our scientific knowledge during the latter years of the nineteenth century. Its discovery, as nearly all our readers know, originated in this city. It continues to occupy a large share of the attention of the clinicians and pathologists of the foremost scientific centers of the world. A very excellent summary of the present state of our knowledge on the subject has just been issued by Drs. Paul Sainton and Dean Ferrand, of Paris. And, not long ago, a most interesting account of a typical and instructive case was published in the antipodal area of our globe, by Dr. E. Angus Johnson. The patient in this case was, as usual, a female, aged 32, who had been married 18 years, but still remained a nullipara. At the date of her marriage she weighed 7 st., 9 lbs. "Eight years ago she noticed that her stomach was getting larger, and very tender on

pressure (the pain being compared to that of a bruise). Then the hips, chest, arms and legs got bigger; pains of a neuralgic nature under the left shoulder, which have been worse since the influenza; also neuralgic pains on crown of head, across the forehead, and particularly over the left temporal region. There are frequent hot flushes of the face, followed by cold, clammy sensations; also giddy sensations, with a feeling as if she is going to fall backward. Locomotion is difficult, and a very short walk is followed by great breathlessness and palpitation, her nervous equilibrium being upset over most trivial matters. When she 'catches a cold,' the pain in the chest is so severe that she cannot sleep on its account. Standing for any length of time causes severe pain in the ankles and knees (which do not swell); this also prevents sleep." The face is not affected, and on that account has the curious aspect of looking too small. The thyroid gland, so far as its outlines can be made out, appears to be unaffected. The thoracic and abdominal walls present a great deposit of adipose tissue; on the latter "whilst in the recumbent position big folds of fat are produced. This is tender on manipulation or slight squeezing, the pain, as already noted, is likened to that which follows a bruise, the skin bruising on very slightly squeezing it." The temperature and heart's action appear to be normal; pulse 96. The hands and feet appear normal, except for a slight fulness of the thenar, hypothenar and plantar eminences. No muscular wasting can be detected; the headache, palpitation, vertigo and sleeplessness are intensified at menstruation. The *tout ensemble* suggested to Professor Watson, who saw the case in consultation, the happily descriptive epithet of *ambulatory lipoma*. The series of cases collected by Drs. Sainton and Ferrand for their recent communication on Dercum's Disease does not include the Australian one. They were able to find reports of 42, up to the latter part of August of last year. Having been first described in 1888, the amount of attention and comment which it has continuously elicited since that date is a proof of the great interest which attaches to it. And not being a condition in itself destructive to life, there have been but six post-mortem records obtained. The various lesions found in those specimens have entirely failed to illuminate its pathology. The physical character of the fatty deposit presents few, if any, distinctive features. Perhaps the most suggestive is a report of interstitial neuritis affecting the cutaneous filaments, with consequent atrophy, and not involving the nerve-trunks. It must, however, be noted that in six reported autopsies there were lesions of one or more of the vascular glands. In four the thyroid body was the seat of extensive morbid changes; in two, the pituitary. Dr. Dercum found in one case marked atrophy of the columns of Goll, and noted the presence of myelin fibers in the corresponding part of the pia mater. These he regarded as a product of an effort toward regeneration. In his original description of the disease with which his name has now become inseparably connected, Professor Dercum defined it to be a "dystrophy" of the subcutaneous connective tissue of the arms and dorsal region, associated with "symptoms analogous to those of myxedema." It has since been remarked by other observers that dystrophy was an unfortunate term to use, as the condition was rather one of hypertrophy; and, with more justice, that myxedema differs widely in its features, but that having certain points of resemblance, the reference might tend to some diagnostic confusion. Of the cases hitherto reported, the great majority (6 to 1) have been females, and the usual period of occurrence is toward the time of the menopause. Nevertheless, the cases of Hale White and Spiller were observed at the respective ages of 11 and 22; and those of Achard and Laubry commenced at the individual (ripe) ages of 70 and 79. In 1891, Dr. Henry, of Philadelphia, reported the case of a woman of 63, which appeared to resemble the condition described by Dercum. He even expanded the maladroitness comparison

with myxedema, giving the clinical syndrome the appellation of myxedematous paratrophy. But, in the following year, the original describer published another case which he sharply differentiated from myxedema—by the characteristic pains and swellings—and gave the morbid entity the happily descriptive appellation of *adiposis dolorosa*. In 1894, the first French case was published; the Philadelphia cases were recorded in 1895 and 1898; and Dr. Hale White published a true British case in 1899. Since that date, the clinical records of *adiposis dolorosa*, have undergone a process of hyperplasia, almost as significantly rapid as that of its connective tissue—the neurotic land of France almost necessarily supplying a large proportion. The balance of clinical evidence now available clearly goes to show that the theories of a thyroid or pituitary lesion being the essential factor in the production of the pathologic series of changes characteristic of this disease must be given up. In the early years of its history the attempt to separate the essential from the accidental symptoms present in Dercum's disease caused some confusion, which in the presence of the collective record now before us need no longer exist. Two types of subcutaneous fatty deposit are clearly recognizable. The *diffuse* and the *localized*. But there are intermediate and mixed forms. The diffuse engages the trunk, neck and limbs; but always respects the face, hands, and feet. The localized type produces a number of subcutaneous fatty tumors; which might be taken for multiple lipomas, had it not been for the characteristic pain and tenderness and the tendency to form adhesions, both to the skin and the deep structures. The immunity of the face would by itself exclude the diagnosis of myxedema; and taken with that of the hands, feet and abdominal viscera differentiates it from general obesity. The invariable presence of pain and tenderness gives, of course, absolute confirmation. The latter presents variable characters; it is sometimes confined to the affected areas, and sometimes radiates along the course of the nerves. It is also variable in its nature and degree; and in the great majority of instances is intermittent and paroxysmal. In a few of the cases in which multiple swellings existed, some of the tumors were painful while others were not. In certain cases pain was not apparently spontaneous; it was only complained of when elicited by pressure. The skin is, in the early period noticeable over the swelling, but always becomes adherent after a time; and in some instances patches of scleroderma formed over the most prominent parts. Failure of motor power does not appear to be an essential feature at any stage. Nor do the anesthetic patches (or zones) sometimes observed present a distinctive character. No characteristic changes appear in the blood. Various other symptoms which have been noted do not appear to have been more than coincidences. Although with regard to sex and age, the condition displays elective affinity for the menopause, it does not appear to be determined by or accompanied by any special menstrual derangement. Hereditary taint or special constitutional diathesis does not seem to predispose to its development. The only special habit of body which has appeared prominent in this connection is alcoholism, of which there was a history in many of the cases. It is a remarkable fact that in a few cases, the onset of the disease followed with significant promptness the occurrence of local traumatism. In a case published by Eshner, the formation of tumors began from 15 to 20 days after the occurrence of the injury. And a patient of Dr. Féré did not cease to suffer from the local pain which began with the injury till the tumors appeared. Indeed in the light of our present knowledge we may probably—in the absence of ideas sufficiently luminous for translation into English—refer to its pathogeny with the nearest available approximation to truth as a “trophoneurosis;” perhaps some may prefer to explain its genesis in the language of Dr. Sallerin by “*un simple trouble dynamogène du système nerveux*.” Beyond

the effect of anodynes in relief of pain, none of the methods of medication hitherto essayed have given satisfactory results, although temporary diminution of the swellings have been reported in some instances, during the employment of salicylates, arsenic, and thyroid extract, respectively.

REVIEW OF LITERATURE

Mercurial Nephritis.—J. M. Swan¹ reports the case of a woman of 31, who had been treated for a skin eruption several times. It usually disappeared after several months' treatment, to return again some time later. A diagnosis of syphilis by a dermatologist caused her to be put upon a mixture of mercury biniodid, $\frac{1}{2}$ gr., and potassium iodid, 15 gr. thrice daily; she also took $\frac{1}{4}$ gr. of the yellow iodid 4 times daily, and 2 dr. of mercurial ointment daily by inunction. Symptoms of mercurialization several times during the next few months caused temporary cessation of treatment. About the fifth month after beginning on these drugs, edema developed; she had photophobia, headache, dyspnea, increased urination, and precordial pain; the urine contained albumin, casts and leukocytes. A scaly rash covered her body. A condition of renal syphilis was thought to prevail and antisyphilitic treatment was persisted in, in conjunction with digitalis and nitroglycerin. This was continued for 1 week, the patient getting worse steadily; mercury iodid, of which she was now taking 2 gr. daily, was stopped for a week, when inunctions were used for 3 days. The symptoms, which had been slowly disappearing, returned with renewed force, but the eruption did not yield in the slightest. Examination of the urine showed the presence of mercury in large amounts and the diagnosis was modified to mercurial nephritis, the eruption diagnosis to psoriasis. The treatment now tended toward the elimination of the mercury, and the patient steadily improved. Mercury could be found in the patient's urine 13 months after the last dose was given. [E.L.]

The Pathogenesis of Gout.—Chalmers Watson² states that the old theory of the etiology of gout was that a derangement of the intestinal tract with the absorption of toxins was the primary factor in the disease. Since 1847, when Garrod discovered the presence of uric acid in the blood in cases of gout, this old theory was abandoned. In 1901, however, Watson revived the old theory in the following terms: 1. There is ample evidence to prove that uric acid in the blood is not the primary factor in gout. 2. Uric acid can be deposited in the cartilages and other tissues in considerable amounts without the association of any inflammatory phenomena. He says the last named point proves that uric acid is not the factor which causes the characteristic phenomena of gout. He then enters into a discussion as to what the etiologic factor really is, and he believes as before announced that some derangement of the alimentary tract is in reality the cause of the trouble. As evidence in support of this belief he records the postmortem findings in a cock which had died of a typical form of gout in the fowl. The article gives a detailed account of the pathologic findings in the various tissues of the body, which appear to substantiate the autointoxication theory. He further suggests that, in addition to disturbed alimentary canal, bacteria in this canal probably play a large part in the causation of this disease. [A.B.C.]

Roux' Antistreptococcic Serum in Bronchopneumonia.—Bouttiaux³ has employed Roux' antistreptococcic serum in 6 cases of bronchopneumonia and draws the following conclusions from the results: 1. Roux' antistreptococcic serum is of no value in bronchopneumonia complicating whoopingcough. 2. The deaths from bronchopneumonia in whoopingcough cannot be claimed to have been due to the serum as no local reaction was noted at the point of injection; and as the first patient died 8 days after the injection, the second 4 days after. 3. The serum injection produces generally an aggravation of symptoms during the following afternoon, but this is without any importance. 4. In simple primary pneumonia the serum gives good results. 5. The temperature falls about 48 hours after the injection; bronchial breathing may persist for some time. 6.

¹ American Journal of Medical Sciences, 1904, Vol. cxxvii, No. 116.

² British Medical Journal, January 9, 1904.

³ Ann. de la Soc. Med.-Chir. de Liege, 1903, xliii, 615.

The dose of the serum employed at one time is 20 cc. no matter what the age of the child is. 7. The serum has not produced either local or general serious complaints. [E.L.]

Education against Pulmonary and Tuberculous Diseases.—Claude C. Pierce,¹ an assistant surgeon of the U. S. Hospital Service, states that the 4 important factors brought out by the experts in the great congress at Berlin and later at London, are these: 1. Tuberculosis is a communicable disease, due to Koch's tubercle bacillus acting on an organism prepared to receive it, or unable to resist the bacilli when present in large numbers. 2. Tuberculosis is not to any great extent hereditary. 3. Tuberculosis may be prevented by reducing the sources of infection, by improving the environment, by strengthening the individual. 4. Tuberculosis, in many even of its severest varieties, can be cured. He outlines certain requirements, which he thinks should be placed in statutory form in all States. He would make it illegal for any person to spit on any sidewalk, in any church, hotel corridor, theater, grocery, or market, or in any railway station, public building, steamboat, railway car, street car, or licensed vehicle, except in spittoons or other receptacles. It should be the duty of Boards of Health, so soon as notified of the existence of a case of tuberculosis, to take all proper precautionary measures, whether applied to the individual or the house itself, against the spread of disease. He would make it the duty of such boards to distribute to interested parties circulars containing instructions in regard to the sanitary management of the patient, the sick room, and the family surroundings. A proper registration of all cases, with the sanitary history of the infected house, as far as practical, should be kept with the sanitary authorities. Upon the death or removal of the patient suffering from tuberculosis the house or quarters should be thoroughly disinfected by the Board of Health. He suggests the principal modes by which communicable diseases are disseminated, and also prevented, taught in the public schools. [A.B.C.]

Serous Meningitis and Lumbar Puncture.—M. Blumenthal² reports the case of a boy who, 3 weeks after a fall, developed very severe cephalalgia, which existed without interruption day and night for a week. The boy held his retracted head very stiff, and whined constantly; he made a snuffling noise with nose and mouth. Nothing could be seen locally excepting very prominent veins. As nothing seemed to improve his state, a lumbar puncture was resorted to; 40 gm. (1½ dr.) of serous fluid was removed. Within 3 days the boy seemed well. After 14 days the head pains returned; 100 gm. (3½ oz.) was removed this time; perfect recovery resulted. Blumenthal sees in the fall the exciting cause of the condition, but a previously existing and healed rachitis (the boy had markedly bowed legs) leads him to suppose the preexistence of a chronic hydrocephalus as predisposing cause; the possibility of an acute serous meningitis after trauma is also mentioned. [E.L.]

Akinesia Alger.—A case is reported in a child of 10. Only 8 cases are on record in Italy, and these have been adults. Fiorentini³ traces the girl's history, and concludes that the syndrome is a manifestation of hysteria "monosymptomatic" in form; this is also the opinion of other writers. [T.H.E.]

Laughing-gas and Chloroform-ether Narcosis.—After discussing the advantage of the combination of chloroform and ether narcosis, which the Braun apparatus permits us to enjoy, Kroenig⁴ calls attention to the disadvantages of either or both at the outset of the anesthetization, especially the prolonged stage at the beginning, until the patient is under the influence of the anesthetic. He proposes to overcome this by starting the narcosis with laughing-gas. For this purpose he combines the Bennet inhaler with the Braun apparatus. After describing the combination apparatus, the method of application is set forth. The patient is first given pure air to inhale, which quickly sets his apprehension at ease; laughing-gas, which is odorless, is then substituted; after from 40 seconds to 60 seconds the patient is unconscious, and takes the chloroform-ether mixture readily. At the end of 5 minutes, without any struggle whatsoever, the patient is ready for the operation. He has

employed this method successfully thus far in over 500 cases. [E.L.]

The Pancreatic Duct in Relation to Icterus.—Andrea Borri¹ says the pancreatic function is evident on account of its relation to fat digestion, but for control tests the hepatic secretion, as well as that of the mucosa intestinalis, must be considered. The writer gives details of 3 cases, in 2 of which the pancreatic duct was entirely occluded, and in the third, the ductus communis choledochus. By contrast, the separate influences on certain food products is assured. Latest opinions conclude that the pancreatic steapsin saponifies and emulsifies the fats—these being already influenced by the alkalinity of the hepatic secretion. The emulsified fats in turn are acted on by the bile, and the fatty acids reduced to neutral salts of potassium, and especially of sodium. The succus entericus, with the aid of bacteria normally present, is able to convert a small proportion of fats into saponaceous material in the absence of both pancreatic and hepatic products. The intestines absorb none but neutral salts and soaps. These facts are essential to a study of fecal saponaceous matter. In cases of pancreatic insufficiency, in direct ratio will the feces discharge undigested fat, not saponified. In the absence of bile, with the pancreatic juice alone at work, the succus entericus seems to fill, in a measure, the need of an alkaline diluent, but the process of fat conversion is labored; and fecal matter containing imperfectly chosen fat derivatives marks the hepatic neglect; saponification is fairly well under way—but the potassium and sodium compounds deficient. The writer discusses clinical histories in addition, to show that the state of the liver and the pancreas may be indicated to the watchful observer. [T.H.E.]

Hitherto Unknown Effect of Röntgen Rays on the Organism of Animals.—Albers-Schoenberg² exposed male rabbits and guineapigs for varying periods of time to powerful röntgen rays, with the result of depriving them of the power of reproduction; it is undetermined whether this inability is transient or permanent. The general health remains undisturbed. As regards sexual instinct and ability to copulate, these animals do not in the slightest differ from normal untreated animals. This sterility is due to necrostermia, which after some time terminates in absolute azoospermia. Eleven such male animals (5 rabbits and 6 guineapigs) were paired with 14 untreated females for periods varying from 10 days to 5 months, without producing a single conception. Some of these females had borne young ones prior to this period, when being brought together with untreated males. Azoospermia was produced after 377 minutes' exposure, 195 minutes produced oligo-necrostermia. [E.L.]

Intravenous Collargol Injections in Septic Affections.—G. T. Harrison³ reports the case of a woman suffering from pyemia and who under ordinary treatment for the affection was progressively growing worse. She had a serous effusion into the knee-joint, and an abscess of the gluteal region. An intravenous injection of collargol was followed by an improvement in temperature, pulse, and general condition. Two more injections were given in the course of the next 2 weeks. A large abscess in the thigh developed in spite of this, requiring operative interference; an immense quantity of pus was evacuated. From the next day on only serous fluid was discharged from the wound, and it healed very rapidly. The effusion in the knee-joint disappeared spontaneously. The author sees in this, as well as in the rapid healing of the thigh abscess, the action of the collargol, and expresses his belief that it should be used in all septic infections. [E.L.]

The Cause of Turbidity in Milky Ascites Fluids.—J. Joachim⁴ finds that there are collections of fluid, milky in color but devoid of fat, in which the cause of the turbidity is to be looked for in a globulin, which is in firm combination with lecithin, without, however, the presence of free lecithin. He has studied a case in which lecithin could be found in the pseudoglobulin, thus showing that the turbidity is due to the pseudoglobulin, and always to that part of it which is insoluble in water. EDITORIAL COMMENT

Increasing Frequency of Appendicitis and its Causes.—Not only the laity but many members of the medical profession are asking today, why is appendicitis so much more common than it used to be? There is apparently no trustworthy data on which to base an answer to this question. It seems doubtful whether appendicitis is really more common than formerly or only apparently more common because not only the profession is now on the alert to make a diagnosis, but at the present time the majority of people recognize at once the classic symptoms of appendicitis and in many cases insist on operation even against the wishes of their more conservative medical advisers. One cause for appendicitis which we have never before heard mentioned is suggested by Villaret,¹ who states that in Germany many people believe that the increasing frequency of appendicitis is due to more general use of glazed earthen dishes which were not in common use formerly; that splinters are supposed to be broken off these dishes which get into the appendix and cause inflammation. On this side of the Atlantic the distrust of grape seeds is quite general. In a recent address before the Syracuse, N. Y., Academy of Medicine, Dr. Howard A. Kelly said that he had been able to collect reports of over 70 cases in which a pin lodged in the appendix was the cause of trouble, and pins are the most frequent foreign body mentioned in literature as a cause of appendicitis, he facetiously remarked that it would be wise for people to avoid swallowing pins instead of grape seeds in order to avoid the danger of appendicitis. One surgeon of large experience among our acquaintance has a firm belief in the danger of eating too many peanuts. Some have thought that appendicitis has only become a common disease since the appearance of the grip and that possibly there may be some connection between infection with the influenza bacillus and the prevalence of appendicitis. These causes will appear fanciful to most people and of the many other causes which have been suggested it is often difficult to select an adequate one to account for the origin of a given case. Probably there are a great number of factors predisposing to, or directly causing most cases of appendicitis and in many it is impossible to definitely estimate the relative importance of such causes. Villaret further contributes to the question of appendicitis by quoting the statistics of the German army during the past 27 years. He believes that in the past the conditions most frequently mistaken for appendicitis were various stomach and liver diseases and peritonitis. During the 27 years from 1873-74 to 1900-01 the percentage of cases of appendicitis has increased in relation to the whole number of soldiers in the German army about 70%, while the number of cases reported as stomach, liver, and peritoneal inflammations has decreased almost correspondingly. We take it, of course, that Villaret means appendicitis when he speaks of perityphlitis, the old-fashioned erroneous designation of this disease which is so commonly used in Europe. These statistics have some value inasmuch as the number of soldiers in the German army has ranged from 298,876 in 1873 to 528,489 in 1901. This number of men is large enough to give quite reliable data. Whether appendicitis has really greatly increased in prevalence in recent years will perhaps never be definitely settled, but we do know that it very common at the present day, and whatever may have been the frequency in the past, or whatever may be the most important etiologic factor causing the inflammation at present, there is no doubt in the minds of the majority of the profession in America today that our greatest

safety lies in early removal of the offender when it gives trouble. Timely operation gives us definite proof of the frequency of appendicitis and this evidence of the accuracy of diagnosis was not at hand in the olden times when the diagnoses of "inflammation of the bowels," idiopathic peritonitis and stomach and liver trouble were more frequently given than now.

REVIEW OF LITERATURE

Treatment of Tuberculous Peritonitis.—A. Groves¹ says that if direct infection of the peritoneum can be demonstrated from a primary focus, this should, if possible, be removed, as a preliminary measure. Emphasizing the value of sunlight in the treatment, he states that the abdominal walls should be exposed to the direct action of the sun's rays daily for hours at a time. When medical measures fail, the question of operation comes to be considered and this is one of the conditions in which early operation is seldom to be advised. When other organs are involved operation is indicated only to give temporary relief from large accumulations of fluid. Laparotomy is followed by the best results in chronic cases when there is a quantity of fluid, but the disease is quiescent. In certain of the cases, cure follows simple tapping, hence when cure follows or appears to follow laparotomy it may be that the disease has run its course and the operation only removes the products of the disease, a most necessary thing. Chronic cases cured by either laparotomy or tapping and acute cases terminating in death, despite operation, are cited. In conclusion, the writer states that an experience of 30 years of practical work shows that where previous arrest of the disease has been accomplished recovery follows operation; where the disease is acute, no improvement results. [A.G.E.]

Excochleation of the Prostate.—Riedel² has excochleated the prostate in several cases with success. The operation is performed by making an inverted T-incision through the structures of the perineum, the patient being in the lithotomy position. In this way the prostate gland is exposed without injury to the rectum and urethra. The lateral lobes are not exposed, their capsule opened, and portions of it removed with a sharp spoon. He advises the performance of the operation at a time when the bladder is still healthy, and especially therefore, in younger men who are just beginning to be disturbed by the condition. It may be necessary in such cases to repeat the operation on account of a regrowth of the glands. He relates the details of the cases of 5 patients; the first had catheterized himself for 2 years. On the evening after the operation he voided his urine spontaneously. He has remained well for 15 months. The second patient had a 2-chambered bladder as the result of a diverticulum. This was not recognized at the time, and he died during the second operation. Patient number 3 was improved slightly; in numbers 4 and 5 the operation was successful even though the urethra was injured. [E.L.]

Surgical Interference in Renal Affections, Especially for Nephralgia and for Idiopathic Hematuria.—A. Perez³ says our views are still empiric. But the cases observed indicate the advantages of the "Edebohls' procedure." Israel gives 14 cases of which 3 were fatal. He operates under the opinion that congestion exists. The incision through the renal substance allows immediate relief. And later there is established an anastomosis between the inner and surrounding renal circulations which acts to reduce the possibilities of a return of the morbid state. Harrison notes improvement in bilateral cases when but one kidney is interfered with. He explains the improvement by the assumption that when one kidney acts normally it will exert a beneficial effect on the other. Leguen and others operate when there occurs any sudden arrest of kidney excretion. Pousson claims there is a synergic function which unites the 2 organs. When one kidney exerts a malefic influence through an incurable lesion, it is wiser to do a nephrectomy than to permit injury of the other organ. Rovsing does not believe that the congestion occurs entirely from inter-

¹ Deutsche medizinische Wochenschrift, 1904, Vol. xxx, p. 16.

² Canada Lancet, February, 1904.

³ Deutsche medizinische Wochenschrift, 1903, No. 44.

⁴ Il Politecnico, Rome, No. 5, 1904.

nal causes. The pressure on the kidney by its capsule is an energetic, additional source of renal disease, and a division of the capsule very satisfactory. The fact that the capsule may, or may not, be adherent is important. Many surgeons agree as to the value of the surgical treatment regardless of the cause of the trouble and of the exact method of rehabilitation. Among these: Lennander, Kuemmel, and Rumpel. It is usual in most idiopathic cases to effect a permanent cure. Edebohls records 51 cases of nephritis in which about 10% showed great improvement, if not cure. In 22 other cases much relief was experienced. The writer will give personal results in a subsequent paper. [T.H.E.]

Leukocyte Count as an Aid in Decision for or against Immediate Operation.—E. S. Van Duyn¹ reports 50 cases in which it was endeavored by the leukocyte count to determine the presence of infection, its severity, its extent, and progress, and the necessity or urgency for operation. Of the 50 cases, 20 showed no pus and 30 contained pus. In the first 20 the count ranged from 5,600 to 14,600; in 11 of them the count was below 9,400, while the higher counts without pus in the remaining 9 were explained by other conditions present. The count in the 30 pus cases ranged from 7,000 to 37,000. Enough of these were below the maximum count in the cases not containing pus to make 40% or 80% of the entire series overlap. This would seem to preclude the possibility of determining accurately, from the leukocyte count, the character of the infection present. But Van Duyn shows that by dividing these cases into series according to the presence of factors which are known to affect the leukocyte count, they can be reduced to remarkably uniform findings instead of contradictions. He then emphasizes the necessity of the surgeon knowing and considering these accessory factors when interpreting the leukocyte count in any individual case. [A.G.E.]

Strangulation of the Ileum in 2 Places.—Max Hofmann² describes a case of this rare condition in a woman of 64, who for 20 years had suffered from an inguinal hernia. A day and a half prior to her first examination the hernia became painful, tender, and swollen. For 2 days she passed neither gas nor feces. There was no vomiting nor eructations. The patient was operated upon, but died 21 hours later. One part of the incarcerated intestine was 13 cm. (5 in.) from the ileocecal valve, while the second portion was 50 cm. (20 in.) farther up. Hofmann could find only 6 similar cases in the literature. [J.H.W.R.]

First Case of Successful Ligation of Aneurysm of the Hepatic Artery.—H. Kehr³ reports the following case: A man of 29, who had been suffering with cramps of the stomach for some time, was taken suddenly with jaundice and bloody vomiting. The liver was enlarged. Attacks of colic, jaundice, and hematemesis occurred frequently during a period of 15 months, since which time the patient complained only of constant pressure in the hepatic region. Operation revealed an aneurysm of the right branch of the hepatic artery, which necrosed and connected with the cystic duct. The gallbladder was tapped and then removed; the cystic duct was split open, and the hepatic artery ligated with double threads in 2 places, and severed between. The aneurysmal sac was then fully exposed, cut open, and cleaned out. The wound was firmly tamponed; the liver closed with several sutures, and the wound closed. The patient made a good recovery, only a very superficial part of the liver becoming necrotic. This good result was probably due to the fact that the long duration of the condition produced a good collateral circulation. The diagnosis in this case was only made on the operating table, but should this symptom-complex (colic, icterus, gastric hemorrhage) occur again, Kehr would feel justified in diagnosing hepatic aneurysm. [E.L.]

Interilioabdominal Amputation for Sarcoma of the Ilium.—W. W. Keen and J. Chalmers DaCosta⁴ report this case, the patient being a man of 42. Keen describes the operation employed—a modification of that of Savariaud, with a long internal flap. The internal iliac artery, but not the vein, was

ligated. The horizontal and descending rami of the pubes were divided and the ilium sawed through from the crest to the great sciatic notch. The operation consumed 1½ hours. The patient reacted quite well from the operation but died 33 hours later from almost complete suppression of urine and unexpected gangrene of the parts supplied by the internal iliac artery. Experience in this case leads Keen to concur with the views of Morestin published in a recent article, at least in the disarticulation at the hip and sawing of the bone. He is, however, still more inclined to abandon the interilioabdominal operation in cases in which it is possible to substitute resection of more or less of the innominate bone, even up to its entire removal, without amputation of the entire lower extremity. The tumor in this case proved to be an osteosarcoma. The paper contains a table of all the cases of the extensive operation in question that are on record—16 for sarcoma and 3 for tuberculosis. Only 6 terminated in recovery of the patient. [A.G.E.]

New Method for Cholecystotomy.—W. W. Lynch¹ removes the stones from the gallbladder in the usual manner, but in closing the wound he first closes the incision in the gallbladder except a small opening for a tube. He then closes the peritoneum with a continuous suture except at the upper extremity of the wound, where he attaches the edges of the peritoneum to the gallbladder by a circular suture, which surrounds the opening left for the tube. The parietes are then closed as usual, except that untied sutures are placed over the opening for the drain. A tube is carried into the gallbladder and this is surrounded by gauze which lies in the wound but is extraperitoneal. In from 48 to 72 hours all drain is removed and the sutures tied down. The operation has the following to commend it: 1. The parietal membrane yields with the movements of the gallbladder during respiration, coughing or vomiting and the tension thrown on it is probably no greater than that used while suturing it. 2. The peritoneal membrane rapidly and abundantly throws out a plastic exudate, strengthening the walls of the fistula and barricading the general peritoneal cavity against extravasation and infection every hour after the operation. [A.B.C.]

Fistula of the Urachus in an Adult.—Emil Stangl² describes a case of congenital fistula of the urachus in a man of 21. The umbilical region was prominent, and the umbilicus itself larger than normal. The fistula closed spontaneously when the patient was 14 years old. Until that time when the bladder was filled the urine dropped from the navel. Seven years later the patient began having pain in urination, associated with a swelling to the left of the navel, which contained fluid. From the umbilicus flowed an abundant red foul-smelling secretion. The entire inflamed urachus was removed, and the patient made a speedy recovery. [J.H.W.R.]

Direct Pains Associated with Appendicitis.—W. D. Spanton³ states that the pain of appendicitis is, in many instances, referred to the epigastrium. This epigastric pain is almost invariably associated with peritonitis and is one of the most valuable indications for the operation. He calls attention to the frequency of appendicitis occurring at the catamenial period in young women. A goodly proportion of the cases of appendicitis with localized swelling without marked constitutional symptoms recover without operation. The absence of such swelling, however, indicates little, for the appendix may be gangrenous and hidden in the pelvis or it may be behind the ileum. In regard to operation, every case must be a law unto itself. Several rules may be laid down. With definite indication of general peritonitis or of increased prostration no time should be lost; when the temperature rise and fall, is irregular with weakening of pulse and increase of abdominal tension operation is demanded; likewise any persistent sickness, obstinate constipation with typhoid symptoms, localized swelling, painful and tender to touch with steady rise and fall of temperature denoting pus, of course demands operation. Many of these pus cases are extracecal and can safely be opened and drained from outside the peritoneum. Far more lives are lost by deferring operation until it is too late than by operating unnecessarily early. [A.B.C.]

Fibromas of the Spermatic Cord.—A. Bruneau and H. de Satriano,¹ in the report of a fibroma of the spermatic cord, state that the condition is a rare one, only 4 classic cases being previously recorded. One other doubtful case is mentioned and one of a fibrofatty tumor. The personal case reported was in a man of 45, who gave no history of previous trauma. The tumor was 12 cm. (5 in.) long and had an average diameter of 5 cm. (2 in.). The weight was 190 gm. (6 oz.). Microscopic examination showed it to be a pure fibroma. The subjective symptoms of these tumors are usually uneasiness with a dragging sensation. Rarely there is violent pain, as in one of the reported cases. The growth is slow and the general health of the patient is not affected. The diagnosis is usually easy. When the tumor is of inguinal origin and projects from the anterior orifice of the canal, it may be impossible to differentiate it from a hernia. The prognosis is favorable, but the possibility of malignant change must be borne in mind. The operation of choice is that of castration, as in the case of tumors of any size dissection from the dissociated elements of the cord is impossible. [A.G.E.]

GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

EDITORIAL COMMENT

The Hemorrhage in Carcinoma Uteri.—Hemorrhage is one of the most constant symptoms of carcinoma of the uterus, as is well known. Sometimes it amounts to an ordinary metrorrhagia, the amount of blood lost is increased and the duration of the menses is longer than usual. At other times the patient suffers from intermenstrual losses of blood which lead her to suppose that the menses occur several times a month. The amount of blood lost is not in large enough quantity to be termed a hemorrhage, and intrauterine and vaginal packing may diminish the intensity of the flux without causing it to entirely disappear. In some cases, however, it may be necessary to operate. Olshausen recommends hysterectomy in cases of uterine hemorrhages which continue in spite of all the usual measures employed to control them, when they are sufficient to endanger the patient's life. The necessity for operating for the hemorrhage rarely occurs, but the early appearance, frequent repetition and increased amount of the blood imparts a rapid progress to the affection. Beside these hemorrhages, which merely belong to the nearly constant symptomatic ensemble of carcinoma of the cervix, one should recollect that these patients are always exposed to accidental hemorrhage of serious proportions. In cases of the cauliflower variety of neoplasm in which the phenomena of necrobiosis reach the highest intensity, a fatigue, a long walk or a rough examination is sufficient to lacerate the tissues and open the bloodvessels. A large artery may thus be opened, the hemorrhage being really alarming, but usually the blood will amount to a free oozing from the veins. The occurrence and gravity of the hemorrhages are consequently an indication for hysterectomy, which not only has an immediate curative action but also a far-reaching one as well, because the recurrence of the neoplasm arises usually behind the vaginal cicatrix, and only ulcerates through the vagina toward the end of the malady. On the other hand, in those cases where the neoplasm recurs in the cicatrix, the hemorrhage will not have its former severity. Hemorrhage is an indication for hysterectomy, which should be undertaken in all cases in which no unfavorable conditions are present which would oblige one to resort to a palliative treatment. Now, when should one interfere? Sometimes the anemia is so marked, the pulse so weak, that the slightest loss of blood would not be withstood, so one must temporize, and by proper treatment directed

to the control of the hemorrhage, and endeavor to strengthen the patient until she has sufficiently recovered as to enable her to stand the shock of an operation. To control temporarily the bleeding, curetment and cauterization of the neoplasm is by far the surest way, and then rest in bed for several weeks with liberal feeding, will place the patient in a condition suitable for the radical operation. Temporizing is certainly prudent, but has the serious inconvenience of necessitating a relatively long period of time, during which the neoplasm progresses with all the greater rapidity, because the patient is in a weakened condition. For this reason one should be encouraged to interfere at an early date, because at present we are better armed against the loss of blood by the use of saline injections, and other methods too well known to require mention here. According to our way of thinking, one should take into consideration two eventualities, namely: Either the neoplasm is at its debut, so that hysterectomy will be easy and rapid, and only a trivial amount of blood is lost, in which case the operation is urgently indicated. The shortness of the operation greatly diminishes the danger of the anesthesia, and if done by the vaginal route, can be accomplished in several minutes. In other cases, on the contrary, the uterus is bound down, and the operation will be long and probably difficult. Under these circumstances a palliative procedure should be adopted, but which will nevertheless have a most effective action on one of the most menacing symptoms, and later the uterus and anexa may be removed, if not too late.

REVIEW OF LITERATURE

The Chorioectodermal Epithelioma.—L. Pick,¹ after a thorough study of the structure of these peculiar growths, reaches the conclusion that there are developed, especially in very young individuals, in the ovaries and testicles, solid cancer-like or solid cystic benign tumors of complicated structure—epithelioma and chorioectodermal cystic epithelioma. The connection of these neoplasms with their congenital teratomatous origin is shown: 1. Through the usual condition of the characteristic syncytium in the tissue of the tumor. 2. Through the general connection with the tissue of the teratoma. 3. Through the direct continuity of tumor cells with other ectodermal cell forms. In these 3 facts, added to other morphologic and biologic differences, lies the complete morphologic and biologic distinction of the chorioectodermal epithelioma as distinguished from the ordinary chorioepithelioma or deciduoma malignum of Marchand. This chorioectodermal epithelioma of testicles and ovaries belongs to the category of benign forms of tumors of congenital origin. [W.K.]

Gloves in Obstetrics.—A. S. Rashkes² has given rubber gloves a conscientious trial in about 600 obstetric cases. Every precaution was taken to insure an unvitiated verdict. The final results as to puerperal fever show that the use of rubber gloves in examinations and operations during labor does not in any way diminish the danger of puerperal fever. Therefore the extreme opinion expressed by Döderlein to the effect that the ungloved hand is the sole source of puerperal infection, must be looked upon as unwarranted. There must be other sources of infection, possibly among others the transmission of germs by the examining finger from the lower into the upper genital tract. [L.J.]

Vesicular Mole of Unusual Size.—T. S. Jones³ reports the case of a woman of 48, who had had 8 children and who when he first saw her had had no menses for some months and was having strong labor pains, with copious, sanguinous discharge, in which could be seen an occasional cyst of the hydatidiform mole. Under chloroform, the mass of cysts was removed from the uterus by the hand, without much difficulty. The whole mass of cysts weighed 5½ pounds, and presented somewhat the appearance of grapes, the cysts being attached one to another, instead of to a common stem, and varying in

¹ Revue de Chirurgie, January 10, 1904.

² Berliner klinische Wochenschrift, February 15 and 22.

³ Journal Akousherstwa, November, 1903.

⁴ British Medical Journal, February 13, 1904.

size from 1½ inches in length to the size of a pin's head. The patient made an uneventful recovery. Five years before she passed a similar, though smaller mole, since which time she had borne a child at full term, though decidedly syphilitic. [W.K.]

Mammary Glands in the Newborn.—H. Raubitschek¹ describes a series of preparations from the mammary glands in the newborn. They go to show that the secretion frequently seen at this age ("hexenmilch") is the result of a necrosis and separation of epithelial cells in the acini and ducts of the glands. The mammary glands at this stage are thus analogous to the sebaceous glands. The secretion of colostrum immediately preceding lactation in the puerperium is of similar origin. The true milk secretion, however, consists of the formation of fat within the cells, without necrotic destruction of the latter. [B.K.]

Extrauterine Pregnancy with a Living Child.—A. Czyzewicz, Jr.,² reports a case of extrauterine pregnancy delivered of a living child at term. A striking point in the case was the fact, that although there was no uterine distention and nothing to be expelled from the uterus, yet the patient suffered the usual typical labor pains. When the abdomen was opened there lay a uterus corresponding in size to a 2-months' pregnancy; and lying between the sacral bone and the uterus, and adherent to its posterior wall and to the entire lower part of the abdominal cavity, was a tense, whitish tumor with many hemorrhagic points on its walls, containing the child and the amniotic fluids. The child still living was extracted, the placenta was removed; but to remove the sac was out of the question because of its extensive adhesions to omentum, intestines and adjacent parts. The loosened parts of the tumor wall were removed, the entire cavity packed with iodoform gauze arranged for drainage, and the rest of the wound closed. Death followed on the third day. The writer concludes that in such cases toward the approaching end of pregnancy, when the operation cannot be easy for the mother, the physician by constant watchfulness must at least aim to secure the conditions most favorable to the life of the child. [W.K.]

General Peritonitis and its Treatment.—J. B. Seldowitch³ graphically presents the contrast between the treatment of peritonitis some 20 years ago and at the present day. It appears that the field of diffused peritonitis has been steadily invaded by the surgeon. Not all forms of the affection, however, have been successfully treated by operation, the so-called gynecologic peritonitis (secondary to gynecologic diseases) having shown poor results under the knife. The author, believing that surgical treatment is the method of choice in purulent diffuse peritonitis caused by gynecologic disease, contributes a considerable statistical material of his own, showing a percentage of cures equal to 29. Although this does not at first thought seem very encouraging, his remarks make it probable that under medical management the rate of recovery would have been far lower. He pleads for more optimism in this field. [L.J.]

Fifty Consecutive Intraabdominal Operations on the Ovaries, Tubes and Broad Ligament.—James Swain,⁴ after citing in detail some of the more interesting of these 50 cases, remarks that he does not allow any sponge or swab to be passed directly from an antiseptic solution into the abdomen; for such solutions are irritating, and by damaging the peritoneal epithelium they hinder the absorptive power upon which we depend for the removal of the exudation which necessarily follows upon operation. Therefore, it is his custom to pass all sponges and swabs through a solution of 1 to 5,000 mercury biniodid, and then to have them washed in a normal saline solution before being used in the wound. In regard to after-treatment, pain after the first 24 hours is nearly always due to flatulence and the best remedy is a turpentine enema which may be given night and morning if necessary. If there are symptoms of peritonitis give a dose of calomel followed by dram doses of sodium sulfate every 2 hours as long as necessary to keep the bowels moved about twice daily. Hot water may be given by

mouth, as it relieves thirst and helps vomiting better than any other remedy. [W.K.]

The Treatment of Dysmenorrhea and Sterility, Due to Stenosis of the Cervix by Incision.—B. Fenwick¹ restricts himself to the consideration of the congenital form, in which the cervix is abnormally long with a "pinhole os." He discusses the operative treatment of the past 50 years, noting that in nearly all cases in any of the methods used the severed lips of the cervix reunited. He presents a method of keeping the lips apart while healing is going on. After dilating the canal he passes one blade of the scissors half way up, that is, from ½ in. to ¾ in., and makes an incision to that extent on each side. He then passes catgut suture through the left side of the anterior lip close to the upper angle of the incision, and then across and through the corresponding point on the right side. A similar stitch is inserted about midway between the former and the tip of the cervix. First the upper, and then the lower stitch is tied. The result is, that the anterior lip is indrawn together, the raw surface being closed completely, while the posterior lip is left flat and open; 2 or 3 wool plugs are tightly applied to prevent hemorrhage and are removed in 16 hours. In all the author's 87 cases the first subsequent period was free from pain, and in 91% the relief has been complete and permanent. Out of 41 cases of sterility 24 have been heard from, and of these, 18 have become pregnant after an average sterility of 5½ years. [H.M.]

Puerperal Sepsis.—P. Horrocks² draws attention particularly to the fact that the streptococcus is the most usual cause of puerperal sepsis. Krönig, in 1894, by careful investigation, found that the vagina was aseptic in all cases of pregnant women not contaminated by digital or instrumental examination, or by coitus. Later, Krönig introduced germs into the vagina and found that they were speedily killed in 2 or 3 days, and that antiseptic douches weakened or destroyed this natural antiseptic action. Hence Horrocks recommends no vaginal examination before or during labor unless some symptoms indicate something abnormal, and then with as great antiseptic precautions as if for an invasion of the peritoneal cavity. Neither does he approve of intrauterine or vaginal douching as routine measures under normal conditions, and 90% of labors are normal. But when in the puerperium abnormal symptoms appear and sepsis develops, then, if sapremic in character, at once introduce the disinfected finger into the uterus and remove any decomposing matter, and follow this by a copious intrauterine douche of some antiseptic solution. He has large experience in antistreptococcal serum in the septicemic type of asepsis, and while in some cases it acted wonderfully well, yet it so often failed that he considers it very unsatisfactory. [W.K.]

Adrenalin in Gynecology.—N. N. Fensmenoff³ has used adrenalin in operating upon the vagina and the uterus. He found that adrenalin has no hemostatic effect on the vaginal mucous membrane. On the other hand, in operations upon the uterus the drug has been very serviceable in stopping hemorrhage. The drug was applied on pledgets of gauze in the strength of 1 to 5,000 or higher (up to 1 to 1,000). The author has also employed adrenalin with success in removing mucous polypi of the cervix, and he intends to try the same agent in the treatment of hemorrhagic endometritis by means of intrauterine injections, etc. He adds a word of caution as to the possible toxic by-effects of the remedy. A number of animal experiments undertaken by the author has also resulted in a favorable verdict for adrenalin. [L.J.]

Disadvantages of Ventrofixation.—G. W. Maly⁴ gives the history of 2 cases of ventrofixation, showing how each patient suffered repeated pregnancies, ending in abnormal deliveries, in most cases, of asphyxiated children. Also in both cases, united with other consequences, there was a hemming in of the intestines. Maly remarks that since in later times gynecologists have ceased to see any pathologic condition in a movable reflexed uterus, but only in the complication of its fixation in the backward position, it may at least be desig-

nated as illogical to convert a fixed retroflexed uterus into a fixed antelexed one, since the pathology lies in its fixed condition. In the second case reported, the os uteri was drawn up above the promontory and the external os uteri, which normally opens in the direction of the pelvic axis, opened backward against the promontory. After the objections mentioned, Maly will not entirely condemn ventrofixation, which at times offers great advantages to the patient, but deems it necessary to call attention to the real dangers and disadvantages which belong to the unphysiologic position of the uterus resulting from this method. [w.k.]

Treatment of Placenta Prævia.—B. A. Libow¹ reviews the accepted methods of dealing with this formidable condition. About 50% of the children are born dead under the usual management, which disregards the fetal life. The ideal method must offer the greatest chance to both mother and child, and such a method is, according to the author, cesarean section. This operation is no longer a novelty in obstetric surgery, and if laparotomy is indicated in extrauterine pregnancy, why is it not called for in placenta prævia, the difference being only in the form of hemorrhage? [L.J.]

After-effects of Deep Cervical Incision in Labor.—Hofmeier² directs attention to the fact that the scar made by a deep cervical incision during labor may prove a great disadvantage in subsequent labor by interfering with the elasticity of the cervix. He reports 2 cases to illustrate this view. In the first case, during labor the severe pain produced no change in the cervix and, had the child been living, he would have performed hysterotomy; but as it was already dead, he dilated the cervix artificially, perforated the head and delivered with forceps with considerable laceration of the cervix. The second case was remarkable because after the deep cervical incision the patient had 2 normal deliveries, but in the third labor there was incomplete rupture of the uterus apparently due to the cervical scar. After some hours of hard labor a dead child was spontaneously delivered with no apparent hemorrhage. A few hours later the patient was in a state of collapse. Under anesthesia the placenta was removed manually when a rupture was found in the uncovered uterine wall just above the cervical scar. After death, which soon followed, examination showed a large subperitoneal hematoma in connection with the tear in the uterus, and apparently this bleeding had begun some hours before the delivery of the child. Hofmeier thinks that since in both these cases very serious complications followed as the result of the cervical incision, only a very great and positive advantage can justify its use. And in each case it would have been advisable to make the incision anterior or posterior, whereby at least the larger vessels would have been avoided and left intact. [w.k.]

Uterine Fibroma and Pregnancy.—M. Lepage³ states that formerly the coexistence of pregnancy and a uterine fibroma was considered very grave. This is an error. When the tumor is small or when it is situated at a favorable point, we should not interfere. It is only when position or size renders the tumor troublesome that it becomes necessary to resort to an operation. Usually the pregnancy goes to term and labor occurs normally. Abortions are but little more frequent than in pregnancy, which is not complicated by a fibroma. Premature labor is perhaps a little more frequent than abortion although the conditions which produce it are rare. After delivery, menstrual disorders and leukorrhea are frequent. If a fibroma is recognized at the beginning of pregnancy, it is well to call the attention of the family to the liability of the patient to these disorders after delivery. The diagnostic sign which should fix the attention of the physician is the suppression of menstruation. A woman who has a fibroma has always suppression of menstruation at the beginning of pregnancy; later, usually at the end of 2 months, it returns in the form of more or less irregular losses; but there is always complete suppression at a given time. The presence of retroversion of the uterus may render the diagnosis difficult. Under these circumstances, a careful examination should be made. The diagnosis is usually easy in the last 4 months of pregnancy, as the tumors

can readily be felt. A pedunculated fibroma may be confounded with an ovarian cyst. Fibromas of the uterine wall may be confounded with the fetal parts. These may be differentiated during uterine contraction; if they are the fetal parts, the nodules will disappear during contraction. The treatment consists in frequent examination of the urine; at the least sign of albumin, a milk diet should be prescribed. The author believes that abortion should not be performed. Surgical intervention is rarely necessary. It consists in removing the fibroma and, if necessary, total hysterectomy. [L.F.A.]

Ovariectomy During Pregnancy.—Karl Heil⁴ adds 66 cases of ovariectomy to the 175 given by Orgler and Gräfe. In the collected cases a mortality of 2.1% shows that the prognosis in ovariectomy is not unfavorably influenced by the contemporaneous pregnancy. The pregnancy was interrupted in about 20% of the cases. Heil concludes that each pregnant woman upon complaint of pain in the uterus, or unusual or irregular pain in other parts of the genital sphere, should undergo a genital examination. The diagnosis oscillates between extrauterine pregnancy on the one hand, and intrauterine pregnancy with an ovarian tumor on the other hand, and celiotomy is absolutely indicated. When possible the tube should be left upon the side operated upon, in order to avoid rupture or tear of the uterus, and for like reasons he prefers the abdominal route. And in his experience the abdominal scar has suffered no injury from the pregnancy or labor. [w.k.]

Gonorrhea in the Female.—In a scholarly series of articles, A. N. Alexandroff,⁵ presents the up-to-date condition of our knowledge of gonorrhea in women. No aspect of the complicated subject is omitted. Speaking of the prognosis, the author takes a position midway between those who assert that the disease can be radically cured in the initial stages, and those pessimists who, like Noeggerath, look upon gonorrhea in women as incurable. Among the therapeutic measures recommended, we find the usual drugs and means, and as a novelty, the warm praise bestowed in the efficiency of the electric current in killing the gonococci. The current has the signal advantage over all other remedies in that it is able to reach the cocci in the deeper structures, beneath the mucous membrane. The details of the electric treatment are promised in a future essay. [L.J.]

The Influence of Gynecologic Operations upon Menstruation.—Josef Bondi⁶ made a special study of the influence of curetment and of one-sided ovariectomy upon menstruation. In the great majority of cases of curetment for menorrhagia, etc., the operation was without any influence upon the type of menstruation, which has been known to return as early as 5 or 6 days after the operation. The mucous membrane, or executive organ of menstruation, may be restored to its normal condition in a very short time, as shown in a case in which the uterus was removed 5 days after the curetment and the mucosa was found completely regenerated. In some rare cases the menses may be delayed for several months, owing to peculiar complications. After onesided ovariectomy, also after other operations, such as those for hernia, for gallstones, or removal of tumors, the menses are usually more delayed, the duration of the postoperative amenorrhea being proportioned to the severity of the operation, the degree of shock, and the vital or recuperative power of the patient; again in some cases the nervous irritability of the patient plays an important role in the matter. [w.k.]

Obstruction in Labor.—Ernst Puppel⁷ reports several instances in which normal delivery was obstructed in different ways, and concludes that since it is known that ovarian tumors may be removed without interfering with pregnancy, therefore, when an incarcerated tumor cannot be replaced, one does well to remove it. Even if reposition is successful, because of changed circulatory and physical conditions there is great inclination to twisting of the pedicle, and this is an added reason for removal of the tumor. So he concludes that all ovarian tumors may be operated upon during pregnancy in order that all obstruction to labor and delivery may be avoided. [w.k.]

REVIEW OF LITERATURE

School Gymnastics.—According to Gulick,¹ the normal development of the body may be left to nature if a suitable environment is provided. The demands of school life are that children shall remain measurably still for 5 hours a day, most of the time seated at a desk. In most schools the desks are not adapted to the length of the spinal column and of the arms and legs of the individual, so that unsymmetric sitting postures are constantly assumed, and growth of the body is correspondingly unsymmetric. The constant sitting still deprives the muscles of that activity which we have shown to be natural to childhood. By insisting on quiet, we have interfered with nature in 2 ways: (1) By taking away a great deal of time that she usually gives to exercise; and (2) by keeping the child for long hours in a more or less unnatural position. The aim of school gymnastics must be to remedy these 2 alterations of the environment which are rendered necessary by the demands of civilization. This combating of the effect of the school desk upon the body can best be done by a few minutes' vigorous exercise of the large groups of muscles at frequent intervals. Except when the ventilation in the building is perfect, the windows should be opened at the end of every hour and the pupils should all be given vigorous exercise for 5 minutes. These exercises should be especially directed to the maintaining of a correct carriage and to the vigorous exercise of the large muscles of the back and thighs. There will naturally be introduced accessory movements of the arms and legs to add variety and increase the interest. The essentials of school gymnastics are correct carriage of the trunk and exercises calculated to strengthen the back and thighs. This will involve increased cardiac and respiratory activity. Such a scheme of exercise as this does not involve difficult exercises or expert teachers; they can be carried on by the regular teachers. They do not make a very heavy demand on the time given to definite intellectual achievement. On the other hand, the attempt to secure by school gymnastics complete motor education must fail, because of the limited time that under the best of conditions can be given to gymnastics during the school period, as well as because of the limited range of material available as compared with that available during play. The complicated motor development, which forms the basis of later skill in life, even including that of an intellectual character, comes chiefly through the development of the hand, lips, tongue, and larynx. The development of the hand, as shown by Dr. Seguin and others, is of the greatest importance; hence, in motor education, manual training, Sloyd, marbles, work with jack-knife, tools, machinery—all seem to have a definite and important place. They are basal to education in the individual as they have been in the race. The object of school gymnastics is to combat the effects of long sitting at school desks. For true motor education, we must depend on play and manual training. Children out of school hours must be given full opportunity to play. In school they must be given opportunity to combat the special conditions presented by sitting still at the school desk. Scoliosis is far more common among girls than among boys. It is rarely found among those who have a fair degree of muscular development of the back. Such simple school exercises as proposed will in Gulick's judgment largely prevent scoliosis in the developing child. When children can have a suitable amount of free play in properly appointed playgrounds, special gymnasiums are not necessary before the twelfth year of age. The same general position might be taken for adolescents, but here, unfortunately, the conditions are somewhat different. Public sentiment does not allow girls to indulge freely in games; the formal exercises of the gymnasium seem to be more suitable. Playgrounds for adolescents are almost entirely eliminated from cities of moderate size, so that in connection with every high school there should be a gymnasium under competent expert supervision, in which all the pupils should take vigorously daily

exercise. This exercise should be directed to general invigorating of the bodily organs rather than to the acquirement of technical skill in any one direction. The kind of technical skill secured by gymnastics is of no particular hygienic or educational advantage; but good carriage of the body, with vigor and endurance, is of the greatest advantage to health.

Therapeutic Applications of Fluorescent Substances.—

It has been found that if fluorescent substances are applied to cultures of living organisms or diseased tissue cells, which are then exposed to the action of sunlight or diffuse daylight, death occurs within a relatively short time; an action which could not be traced to either agent alone, but only to their combination. Toxins and enzymes were robbed of their characteristic properties by this combination. Eosin was found to be the most powerful of these fluorescent substances and to determine the value of this method from a therapeutic standpoint, Tappeiner and Jesionek¹ tested it with epitheliomatous growths, tuberculous disease of the testicle and scrotum, lupus, syphilitic condyloma and chancre. Of the epitheliomas, one as large and deep as a dollar was completely healed after 60 days' treatment; in 2 other cases there was improvement, one having existed 18 years. No untoward symptoms were noted and pain disappeared even before signs of healing showed themselves. In lupus they could not report cures yet, but the result thus far promises the same ultimate result as in epithelioma; only the superficial lesions, however, were influenced favorably. Syphilitic lesions disappeared with marvelous rapidity, and in the 2 cases in which the initial lesion was treated the glandular inflammation disappeared spontaneously. One was not followed by secondary symptoms at all. The eosin was applied in a 5% watery solution by means of a brush and the surface exposed to sunlight; on cloudy days a powerful arc light was used instead. Moist boric acid dressings were applied between treatments. In some cases the eosin was injected subcutaneously with very good result. It was also given internally, but the reports from this are not yet complete. [E.L.] [Morton and Tracy, of New York, have likewise reported good results from the use of fluorescent substances similarly. The matter deserves extended investigation. S.S.C.]

Correction of Flat-foot by Manual Force.—According to H. A. Wilson,² flat-foot offers a good field for forcible manipulations in overcoming the acquired ankylosis resulting from the long-continued altered positions in which the bones have been placed. It is manifestly impossible to induce muscular development in stiff joints. It is first essential to establish full motion preliminary to physical culture. The heel is held fixedly between the thumb and index-finger, which are placed upon the lateral aspect of the os calcis, at the same time pressing the palm upon the posterior superior part of the bone. The other hand is used to draw down the toes and the distal extremities of the metatarsal bones. The thumbs should press upward under the middle of the arch of the foot. Very great force can quite easily be exerted in this manner, often beyond the patient's endurance. Alternate relaxation and application of corrective force will be most effective. This will gradually loosen the fibrous attachments that resist overcorrection. No anesthetic is required except in severe cases, or when it is found difficult to obtain the cooperation of the patient. Still greater manipulative force, when required, may be exerted upon a flat-foot by using the knee as a fulcrum. The operator's hands are placed on the posterior aspect of the os calcis and over the tarsometatarsal articulations, changing the direction of pressure as the exigencies of the case may demand. In still more rigid cases far greater force can be exerted by resorting to the method of Dr. J. T. Rugh, whereby the supplemental force of the operator's legs is utilized. The hands are used to control the force and to add special features as the case may require. The right hand is used with fingers pulling on the outer aspect of the os calcis while the wrist is pushed against the plantar surface of the foot. The other hand is used on the dorsum of the foot in such a manner as to assist in the correction of the deformity and in securing relaxation of the joints.

\$5.00 YEARLY.

"**Simultaneous or Consecutive Polygamy**" is the capital phrase coined by Dr. Dix to denote two methods of reaching the same result. A newspaper caricaturist has hit off the same thought in a picture representing a plebeian old Mormon with his string of wives behind him offering his hand to the haughty millionaire with his string of divorced wives trudging off in the distance. The American does not like the invitation of the Mormon to "Shake, Pard!" The Smoot case at Washington has many lessons, not the least being the attention that is thereby directed to the license that is running riot in the lax divorce laws of our States. It is fast resulting in a condition of "consecutive polygamy," hardly less, and sometimes decidedly not less, injurious to social well-being and the reproduction problems of the race than the Mormon or "simultaneous" method of meeting the problem. If the family is the basis of a healthy and prosperous nation, if the family is the condition of the creation and proper care of children, then it is evident that the Mormon's social philosophy may even be superior to that of some of our American upgrowths. Neither, of course, in any true analysis, will bear the question. The hypocrisy shown by the votes of some of our national legislators, plus their private practises, by no means lessens our duty and shame, but really doubles both.

Sanitary regulation of restaurant kitchens and bake-houses is a public need which our health officers will soon have to undertake. We are making great and expensive attempts to eliminate disease from our public supplies of food, but know absolutely nothing of the filthy conditions of kitchens and bakeries, which cannot help but disseminate disease. The Medical Officer of the City of London recommends a thoroughgoing system of regulations for restaurant kitchens and bake-houses, with inspection by officials, and licenses only of such as govern themselves according to the hygienic rules laid down. These are to concern the scouring and washing of the walls and of the floor; the remedies for damp walls; perfection of drain pipes, and sanitary fittings; the height of the room; the number of cubic feet of air space per person, and the ventilation; the lighting; the temperature; the storage of food and flour; the care of the lavatories; the water-supply; the cleansing of all utensils; the dress and cleanliness of the cooks, etc. As

to kitchens, one of the best methods of securing cleanliness of the cooks and of the food, so long at least as it is being cooked, is the growing custom of doing much of the cooking in the presence of the diner. This plan is extensively practised in Paris, and has worked admirably also where it has been put in practice in our country. We may add that there are certainly the most disgusting conditions and unimagined filthiness in some of our cracker and "ginger-snap" factories. The materials used are sometimes revolting; the workmen are often unimaginably dirty, and not infrequently afflicted with the most loathsome diseases. We have been nauseated by some of the descriptions given by workmen of the practices and conditions that a health officer might find if it were his duty to spy them out.

Boots and Shoes as Disseminators of Disease Germs.—The trailing skirts of women's dresses have been justly railed at as carriers of filth and bacilli, but few have suspected the similar role played by boots and shoes. In cholera epidemics, it is said, a disproportionate number of cases have occurred among boot-blacks. The Mohammedan and Oriental custom of forbidding the worshipers to enter the house of prayer or a guest's house wearing the street shoes, is ascribed not only to the effects upon the floors, etc., that would result, but to the fact that disease is thereby spread. Of course one cannot walk in our dejecta strewn streets and filthy roads without bringing home upon boots millions of bacteria. Not seldom the cleansing of the boots is done in the kitchens or near them. The methods of cleansing moreover are such as to scatter every germ through the air of the house. No one seems to have ever given a moment's thought as to a less offensive and dangerous method of cleansing, blacking and polishing boots and shoes. They are certainly never purified on the inside from the first to the last day they are worn. A more evil-smelling thing than an old boot is hard to find, and odor is not a bad indication of sanitary and unsanitary qualities. He would be a public benefactor who should devise antiseptic methods of cleansing boots and shoes and of blacking and polishing them.

The Meaning of the Word "Cure."—Objection is made from time to time by medical writers to the advertisements of quacks, in which the ability to cure certain incurable diseases, or diseases usually incurable,

is heralded in the newspapers. Doubtless a great deal of harm is done to the ignorant by these mendacious pretenders, but it is well for the profession to look to its reputable members for a correction of such laxity of language. Possibly some are animated by the same spirit as that of Professor James Jackson, of Harvard, to whom Oliver Wendell Holmes referred in one of his essays, saying, "He used to insist on one small point with a certain philologic precision, namely, the true meaning of the word 'cure.' He would have it that to *cure* a patient was simply to *care* for him. I refer to it as showing what his idea was of the relation of the physician to the patient." We have before us the annual report from a large hospital mainly devoted to surgery, in which are tabulated the various operations with their results. The results are classified under four heads—cured, improved, unimproved, died. We find that of 77 operations for carcinoma in various parts of the body, 75 resulted in cure. Of eight operations for sarcoma, all were cured. Of 45 operations for tuberculosis in various situations, 42 were cured. One hundred and thirty-eight operations were performed for the radical cure of hernia, of these 138 were cured. Gastro-duodenostomy was performed in 12 cases, 10 being cured and 2 improved. Gastroenterostomy was performed in 55 cases, of which 46 were cured, 3 improved, and 6 died. Pylorectomy was done in 13 cases, of which 11 were cured and 2 died. A somewhat closer study of these statistics shows the meaning which attaches to the word cure in these tables, as there is no attempt to classify the result in the case of such operations as exploratory trephining without further operation, aspiration and injection of tuberculous abscesses, injection and aspiration of diseased joints, etc. In these cases, the disease was not removable by the knife, and the result of the operation is therefore considered unsettled. It is evident that in every case in which a diseased area was removed by operation, and the patient recovered, the result was tabulated as a "cure." With equal propriety the medical practitioner might tabulate as "cured" a case of pulmonary tuberculosis in which the cough, for which the patient entered the hospital, was for the time being allayed. Such statistics are manifestly of no value whatever. It is regrettable that they are published in this form, as they may serve as the incentive to similar reports from less trustworthy sources where the purpose of the report might be called in question. It happens that the one we refer to comes from a source which does not admit of any suspicion of an improper motive. This makes the fault all the greater. We offer no suggestion as to the manner in which such tabulations should be made. The innocent terms, "operative cure," or "recovered from operation," might be employed; either would convey more of truth than the term here used. We recall the anecdote told by Dr. John Brown of "one of our Gallic brethren," who discovered a specific remedy for a skin disease and used it so vigorously over the patient's surface that the patient perished just when the disease did. "On going into the dead house, our conqueror examined the surface of the subject with much interest and some complacency—not a vestige of disease—or life, and turning on his heel, said, 'Il est mort

guéri!' Cured indeed! with the disadvantage, single, but in one sense infinite, of the man being dead; dead, with the advantage, general, but at best finite, of the scaly tetter being cured."

The United States Association for the Study of Tuberculosis, the foundation stone of which was laid this week in Philadelphia, is, we predict, destined to exercise a profound influence in the profession of medicine and among the people of America. As our readers know, the unfortunate conditions that have arisen in consequence of a multiplicity of societies directly or indirectly interested in the study of tuberculosis, rendered it inevitable that some union should be effected among the best and most representative physicians of the nation in the war against the disease. The names of the formers and committee of the Association mentioned, are guarantees that scientific zeal and the good of humanity are the primary and impelling motives of this newly-formed body, and are not to be secondary to other motives less worthy or at least less partisan and exceptional. The committee to effect the organization is made up of Drs. Trudeau, Sternberg, Welch, Flick, and Biggs. Dr. Osler was made the chairman. There were some who favored joining forces with one or more of the antituberculosis associations already formed, but the wiser conclusion was reached not to do this. As Dr. Ravenel said, "there was no need of taking on the ready-made war" which such affiliation would result in. The committee will meet in June to complete the organization, in conjunction with the Atlantic City meeting of the American Medical Association. It is hardly necessary to urge upon physicians the duty of helping the new Association in every possible way.

The International Role of the Medical Missionary is one that would scarcely have been suspected, but which is manifested in the report of Presbyterian work in Korea. According to *The Outlook*, the first treaty ever made by Korea with a foreign nation was made with America (1882). A young American physician, Dr. H. N. Allen, felt the call to go to a country which was apparently emerging from heathenism, to find out whether his medical skill could keep him there and could perhaps open a path for the preaching missionary to follow. He went to Seoul, the Korean capital, and General Foote, the first American Minister to Korea, promptly made him physician to the Legation. No Korean could object to that. Thus was seized the first opportunity, says the report. A second came two years later, when the Presbyterian Board obtained sufficient funds to found a Protestant mission in Korea. Within a few months thereafter Seoul was distracted with insurrection. In it, Prince Min Yong Ik, a near relative of the King, was terribly wounded and brought to death's door. Though General Foote and all the Europeans fled as soon as possible to Chemulpho, the port of Seoul, Dr. Allen did not. He wrote:

We couldn't if we would and we wouldn't if we could. I came to do just such work. I can't leave these wounded people. . . . We shall live in the Legation with the old flag flying.

As Dr. Allen anticipated, he was summoned to attend the Prince, and withstood 13 Korean so-called physicians,

who wished to pour their black wax into the gaping wounds. They looked on in wonderment while Dr. Allen sewed up the wounds and tied the arteries. A Chinese general was among the bystanders, and had the wit to engage Dr. Allen's services for twenty of his wounded soldiers who had been concerned in the riot. The surgical operations were in the main successful. Thus was opened a third wide door of opportunity. A fourth came when the King, influenced by Prince Min's recovery, proposed to establish a hospital to be conducted on principles of American and European science. Within a few months of its establishment a missionary reported four to six operations every morning and about 70 dispensary patients in the afternoon.

Medical Origin of the Japanese Empire.—One of the traditional accounts of the origin of the Japanese Empire mentioned by the famous Jesuit traveler, Pere de Charlevoix, refers it to the emigration thither of a Chinese colony—under rather peculiar circumstances. Sinosik was ascended the throne of China in the year 246 B. C., and at once entered on a career of cruelty and tyranny. He was, nevertheless, most anxious to enjoy the privileges of his position for as long a period as possible. For the purpose of endeavoring to obtain some specific agent by which the duration of human life could be prolonged, he dispatched trusted messengers and explorers into all the countries with which he held any communication, or of the whereabouts of which he could obtain any knowledge. Taking advantage of the circumstances, one of his medical attendants—who was living in hourly dread of a sudden sentence of death, told the Emperor that he had learned that such an agent existed in the juices of a plant which grew only in the islands which now form the Japanese Empire. The plant in question was also reported to be one of so delicate structure and sensitive nature that, if not plucked with pure hands and special precaution, it would lose all its mysterious virtues before arriving within the limits of the Chinese Empire. It was suggested that 300 young men and the same number of girls—all of spotless physical health and moral purity—should be selected to proceed to Japan for the purpose of procuring a sufficient supply of the precious plant. The suggestion was promptly acted on. The medical adviser also patriotically volunteered to conduct the expedition himself, and the offer was accepted. The expedition embarked, as speedily as possible, for the Japanese Islands, but not one of its members was ever seen within the bounds of the Chinese Empire again. The previously unoccupied parts of Japan were rapidly populated with a race more fresh and vigorous in body and mind than the average inhabitants of the land of the "Celestials" itself! The medical chief of the expedition of course created himself king of the country, and soon had a magnificent palace erected for his residence, which he called Kanjoku (*i. e.* "grande maison, semblable aux cieux"). We are further told that the Japanese mention the historic fact in their annals; that they point out to visitors the spot on which the medical founder of their empire landed; and also show the ruins of a temple which was erected in his honor.

Japanese Medicine and Surgery.—Like their Chinese neighbors, the Japanese—up to the time of their recent adoption of western civilization—practised medicine a good deal, but surgery hardly at all. In fact, there were no recognized surgical practitioners. Their surgical armamentarium—like that of the practitioners of the Celestial Empire—consisted almost, if not wholly, of the *acupuncture needle* and the *moxa*. Their medical practitioners were also druggists and botanists. Each was accompanied in his rounds by an attendant, who carried a small chest in which were 12 drawers. Each of the latter was furnished with 144 compartments containing herbs and drugs. After examining a patient, they selected from this reservoir the required remedies, and prepared and mingled them *secundum artem*. Their science of the pulse was the most complex of any known to medical history, except, perhaps, that of their Chinese neighbors. An examination of the pulse occupied half an hour; at the conclusion of which they professed to know all the conditions and the causes of the malady. As a rule, they used but few remedies. They never let blood. They gave their patients none of the ordinary cooked forms of diet—on the ground that the stomach in diseases was unable to digest anything suitable to the healthy state. Otherwise, they gave them as far as possible what they wished for; relying on the view that nature was always the safest adviser, and never demanded what was hurtful to the constitution. The great object of their practice was the prevention of disease; and to this they believed that nothing contributed more effectively than the frequent use of the bath. There were three varieties of smallpox distinguished in Japanese practice. The first corresponded to that known in Europe by that name. The second appears to have been identical with our measles. The third was a special disease of the country—characterized by an eruption of "pustules aquenses," which Pere de Charlevoix was disposed to attribute to the excessive use of cold drinks by the Japanese. None of the varieties appear, however, to have been regarded as a very fatal disease. According to the early Japanese explorer, Koempfer, the only treatment that was considered necessary was to envelop the patient in red cloth. This traveler states that when one of the family of the Emperor was attacked with smallpox, not only was his bed and the walls of the bed-chamber curtained with red, but all the attendants were obliged to wear garments of the same hue. An interesting anticipation, indeed, of the experimental practice of the English John of Gaddesden, and its recent resuscitation, on the most advanced scientific grounds, by some European and American physicians!

R. The Bicycle.—With the opening of spring it is felt that there will be an end of the overlong period of fashionable disapproval of the bicycle. There is no instrument capable of giving so much exercise, movement, and fresh-air breathing, at so little expense, as the bicycle. The opinions of many physicians, educators, etc., are unanimous in urging the readoption of this hygienic device for many kinds of disease and as an antidote for the long winter's insanitary life. A capital article has been published by Dr. Gulick,¹ of

¹ Boston Medical and Surgical Journal, January 14, 1904.

New York, which epitomizes the medical arguments under the title of *The Bicycle as a Therapeutic Agent*. The author shows a most commendable caution in advising against the ill-considered or heroic doses of this therapeutic agent, and urging discrimination and professional guidance in this excellent new article of the modern materia medica. But under wise limitations all will agree that it should be more frequently prescribed.

Notes on Beriberi in the Malay Peninsula and on Christmas Island.—In these notes, Herbert E. Durham,¹ of the Beriberi Commission of the London School of Tropical Medicine, records numerous personal observations, and some that were communicated to him by other observers, the voluminous literature of the subject being as far as possible excluded. His very readable article contains many points that may be of service in aiding to elucidate the nature of this obscure disease, the cause of which is not claimed to have been discovered. The notes are made up of considerations under the following headings: Conditions of life affecting the prevalence of beriberi; experiments on animals; observations on man; remarks on the epidemiology of beriberi; current theories of the epidemiology of beriberi. Many of the notes are exceedingly suggestive, although not proving any theory of the cause of the disease. We present in full the conclusions of Dr. Durham as being one of the most recent contributions to the literature of beriberi, and a conservative summary of what we regard as a most rational and commendable series of observations:

It would seem, from my observations, that certain of the current theories of the causation of beriberi will not account for the conditions which have been encountered by me. The dietetic or physiologic, the unsound food, the arsenical, and the emanation theories all appear to be insufficiently in accordance with the attendant circumstances to have accounted for the spread of the disease. It is suggested that certain articles of diet, by virtue especially of containing phosphorized and fatty matters, may tend to ward off the disease when given in sufficient amounts. So far as there was any semblance of a positive result in the observations, it is suggested that beriberi is communicated from person to person more or less directly, or through fomites as an actual infection. This infection is not of the nature of a septicemia (since the internal organs at death prove sterile), but to a surface condition about the upper air passages. From the observation of the throats of a number of patients, it is surmised that the redness which is therein seen, especially in early cases, may be intimately connected with the disease. The appearances and disappearances of beriberi and the more or less seasonal waves of prevalence of the disease are not unlike those which are seen in the case of the infective diseases which we meet with in this country. The proneness of the newcomer to suffer, fits in also with such a view. The difficulty in tracing out the source of infection in a disease like diphtheria is often great, especially since we know that the causative organism may be carried by unsuspected refractory or immune persons or animals.

With considerations such as these it is held by the writer that there is no inherent impossibility in explaining many of the circumstances connected with the spread of beriberi. Observed facts seem to show that beriberi should rather be considered in the light of a "gang" or "institutional" disease than as a "place" or "house" disease.

BOOK REVIEWS

A Manual of General Pathology.—By SIDNEY MARTIN. Philadelphia: P. Blakiston's Son & Co. 1904.

The basis of this recent addition to the list of textbooks on pathology is the lectures on General Pathology delivered at University College during the past 6 years. The author states that it is a book for students, the aim being to furnish such an account of the processes of disease that the student may be enabled to follow the study of scientific medicine. The first chapter is devoted to the consideration of inflammation, the second to pyrexia; the four following chapters deal with infection in its various phases, 34 pages being devoted to the question of immunity. This difficult subject is admirably presented, the underlying principles being concisely stated instead of dealing with the various theories, although the latter, principally Ehrlich's, are briefly set forth. Degeneration and Regeneration are then discussed, as are changes in Circulation and Respiration; changes in the Blood occupy several chapters, many points usually referred to special pathology being very briefly considered. Chapters on Disease of the Liver, Kidney, and Ductless Glands, on Metabolism, and Disease of the Nervous System complete the book. In many respects it is a very good book for students beginning the study of pathology; it is well written, concise, plain; it shows evidence of having been written by an excellent teacher. We wish it were possible to endorse the illustrations as we have the text. But many of them are disappointing. This is particularly true of those intended to illustrate tissue changes in the various conditions discussed. We hope that this defect will be remedied in future editions of the work.

A Nonsurgical Treatise on Diseases of the Prostate Gland and Adnexa.—By GEORGE WHITFIELD OVERALL, A.B., M.D. Chicago: Rowe Publishing Co.

Though this book is written by an ardent advocate of the use of electricity in diseases of the prostate, it does not present the earmarks of medical quackery that is so characteristic of many of the present day brochures along somewhat similar lines. The author applies the combined properties of medicine, electrolysis, and cataphoresis in many prostatic conditions for which others resort to surgical measures. For some neglected conditions he also recommends the knife. The first 7 chapters of the book, which contains 207 pages, are devoted to a consideration of the various inflammations, neuroses, and hypertrophy of the prostate and to the seminal vesicles. An appendix of 2 chapters is occupied by the discussion of electrophysics. Many case histories are related. Electricity is not vaunted as a cure-all. The book may be recommended as a contribution to the results of conservative treatment of diseases of the prostate by one who recognizes the limitations of the means that he employs.

A System of Physiologic Therapeutics.—A practical Exposition of the Methods, other than Drug-giving. Useful for the Prevention of Disease and in the Treatment of the Sick. Edited by SOLOMON SOLIS COHEN, A.M., M.D. Vol. VII. *Mechanotherapy and Physical Education including Massage and Exercise.* By JOHN K. MITCHELL, M.D. And *Physical Education by Muscular Exercises.* By LUTHER HALSEY GULICK, M.D. P. Blakiston's Son & Co., Philadelphia, 1904. Eleven volumes, \$27.50.

This volume comprises a discussion of a variety of subjects: The principles, methods, and therapeutics of massage, and exercise as a remedial measure, by Dr. John K. Mitchell; physical education by muscular exercise, by Dr. Luther H. Gulick; orthopedic apparatus, by Dr. James K. Young; corrective manipulations in orthopedic surgery, by Dr. H. Augustus Wilson; and physical methods in ophthalmic therapeutics, by Dr. Walter L. Pyle. The motive of the volume is well expressed in the following sentence from the preface: "Exercise as a therapeutic method has suffered so much discredit from the wild theories and the fantastic and exaggerated overstatement of its value by excited enthusiasts that any one who would write usefully on it must constantly endeavor to make his work not only precise and scientific, but modest and rational

in its claims and practical in its methods." So ample has been Dr. Mitchell's experience that what he has to say on the technic and effects of massage, and on the therapeutics of general and local massage, may well be regarded as authoritative. Such are the interest and importance attaching to his remarks concerning exercise as a remedial measure that they must be read to be appreciated. They comprise a consideration of the methods and effects of exercise, free work for home exercise, systems of physical culture, exercises for obesity, gout, heart disease, and deformities, precision exercises in tabes dorsalis and infantile spastic paralysis, and training for deficient function. Concerning the osteopath and osteopathy ("rather rude massage"), he says: "It hurts his" (the osteopath's) "feelings to call the proceeding massage, and it is indeed rather hard—on massage; but that is what it is—a fact which is not altered by the claim of its having been invented in Missouri." Dr. Gulick's two chapters on exercise and development, and materia gymnastica, sports and games, and systems of gymnastics, are not only interesting and instructive, but also opportune. The editor has been led to give them a separate place "in order to emphasize the importance of the theoretic views advanced by Dr. Gulick, especially as to the correlation between the development of the race and that of the individual, and the necessity for guiding the physical training of individuals on evolutionary and historical lines." The special chapters by Dr. Young, Dr. Wilson, and Dr. Pyle are of a high order of merit. Dr. Wilson's discussion of corrective manipulations in orthopedic surgery, in which he discusses, among other topics, the Lorenz method of reducing congenital dislocations of the hip, will be read with interest, and Dr. Pyle's chapter will be generally conceded to be a conservative statement of the indications for, and the results to be expected from, the use of physical methods in ophthalmic therapeutics. The value of the volume is much increased by a large number of excellent illustrations.

A Handbook on the Prevention of Tuberculosis.—Published by The Charity Organization Society, New York City, 1903.

The contents of this book make up the first annual report of the Committee on the Prevention of Tuberculosis of The Charity Organization Society of New York City. This committee consists of 16 physicians and 16 laymen, all of whom are to be congratulated upon the work accomplished during their first year. The first task assigned the committee was an exhaustive investigation of some of the social aspects of tuberculosis. The result of this, based on a study of statistics, takes up about 80 pages of the report. The remainder is devoted to articles on various aspects of the tuberculosis problem, particularly the prevention, a list of lectures delivered under the auspices of the society, plans for municipal sanatoriums, a partial list of hospitals and sanatoriums for the tuberculous in the United States and Canada, and a brief list of important works regarding tuberculosis. The handbook will prove of value to those contemplating similar organization and also as a means of general education.

Die Faeces des Menschen in normalen und krankhaften Zustände, mit besonderer Berücksichtigung der klinischen Untersuchungsmethoden.—By PROFESSOR DR. AD. SCHMIDT and DR. J. STRASBURGER. August Hirschwald, Berlin, 1903, pp. 325.

This, in many respects one of the most valuable, if not the most valuable, contribution to our knowledge of the feces, is now completed. The entire subject is dealt with systematically. Part I comprising a discussion of the macroscopic examination of the feces; Part II the microscopic examination of the feces; Part III the chemic investigation of the feces, and Part IV the microorganisms of the feces. The work represents in large part the result of original observations; but the thorough consideration of the literature and the many references injected throughout the text add materially to the value of the book as a work of reference. To the student and general clinician the book will appeal with much force, and there is scarcely a physician that would not be much benefited by a reading of the many diagnostic observations appended to the discussion of almost each phase of the subject of the feces in normal and dis-

eased conditions. A number of excellent illustrations add much to the elucidation of the text and the attractiveness of the volume.

A Laboratory Manual of Physiologic and Pathologic Chemistry.—By DR. E. SALKOWSKI. Authorized translation from the second revised and enlarged German edition by W. R. Orndorff. John Wiley & Sons, New York.

English laboratory workers owe a debt of gratitude to Dr. Orndorff for his translation of Salkowski's manual of chemistry. The ability of the author is well known and the translator has made valuable additions and changes to adapt the book more thoroughly to workers in this country. That part of the original volume dealing with inorganic chemistry has not been translated. The arrangement of the text is the best that we have seen. The points to be investigated under each subject are outlined as headings of chapters and the directions are models of brevity and clearness. Nearly 100 pages are devoted to quantitative analysis. Appendices contain lists of reagents, elaborate tables of specific gravities and of international atomic weights. The book should be in the armamentarium of every laboratory worker.

First Report of the Trypanosomiasis Expedition to Senegambia.—By J. E. DUTTON and J. L. TODD. Longmans, Green & Co., London, 1903.

This report is Memoir XI of the Liverpool School of Tropical Medicine, and is a further instance of the valuable work being done by that institution. It includes a description of laboratory methods of studying the trypanosoma, the distribution and prevalence of human and of equine trypanosomiasis in the Gambia, with report of cases, the morphologic characteristics of the parasites, and the results of inoculation experiments. Elaborate studies of human blood are detailed. The report contains many tables dealing with the experiments, and several colored plates of the parasites. While later investigations have still further extended our knowledge of this disease, the present report will remain as one of the most valuable contributions to the brilliant series of studies that are tending toward the determination of its true nature.

BOOKS RECEIVED.

[Prompt acknowledgment of books received will be made in this column, and from time to time critical reviews will be made of those of interest to our readers.]

Transactions of the Luzerne County Medical Society for the year ending December 31, 1903. Volume xi. E. B. Yordy Company, Wilkesbarre, Pa.

Transactions of the Maine Medical Association, 1903. Volume xiv. Part III. Stephen Berry, Printer, Portland, Me., 1903.

A Laboratory Manual of Physiologic and Pathologic Chemistry: For Students in Medicine.—By E. SALKOWSKI, M.D., Professor in the University, and Director of the Chemical Laboratory of the Pathological Institute, Berlin. Authorized translation from the second revised and enlarged German edition. By W. R. ORNDORFF, A.B., Ph.D., Professor of Organic and Physiologic Chemistry in Cornell University. With 10 figures and a colored plate of absorption spectrums. First edition. John Wiley & Sons, New York; London, Chapman & Hall, Limited, 1904.

Progressive Medicine, Vol. I, March, 1904: A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences.—Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Octavo, 337 pages, 7 illustrations. Per annum, in four clothbound volumes, \$9.00; in paper binding, \$6.00, carriage paid to any address. Lea Brothers & Co., Publishers, Philadelphia and New York.

New Eclectic Medical Practice Designed for Students and Practitioners.—By H. T. WEBSTER, M.D., Professor of the Principles and Practice of Medicine in California Medical College. Volume I. Webster Medical Publishing Company, Oakland, Cal.

Obstetrics for Nurses.—By JOSEPH B. DE LEE, M.D., Professor of Obstetrics in the Northwestern University Medical School, Chicago; Lecturer in the Nurses' Training Schools of Mercy, Wesley, Provident, Cook County, and Chicago Lying-in Hospitals. 12 mo. of 460 pages, fully illustrated. Philadelphia, New York, London: W. B. Saunders & Co., 1904. Cloth, \$2.50 net.

A Practical Treatise on Nervous Diseases: For the Medical Student and General Practitioner.—By F. SAVARY PEARCE, M.D., Professor of Nervous and Mental Diseases in the Medico-Chirurgical College of Philadelphia; Fellow of College of Physicians of Philadelphia; Neurologist to the Philadelphia and Howard Hospitals, etc. With 91 illustrations in the text, many in colors. D. Appleton & Co., New York and London, 1904.

Saunders' Medical Hand-Atlas: Atlas and Epitome of Operative Gynecology.—By DR. O. SCHÄFFER, of Heidelberg. Edited with additions, by J. CLARENCE WEBSTER, M.D. (Edin.), F.R.C.P.E., Professor of Obstetrics and Gynecology in Rush Medical College, in affiliation with the University of Chicago. With 42 lithographic plates in colors, many text cuts, a number in colors, and 188 pages of text. Philadelphia, New York, London: W. B. Saunders & Co., 1904. Cloth, \$3.00 net.

AMERICAN NEWS AND NOTES

GENERAL.

Requests to Charity.—**Stamford, Conn.:** By the will of Mrs. Mary Hoyt, a bequest of \$10,000 is given to St. Christopher's Home, and \$5,000 to the Flower Hospital, New York.

American Neurological Association has fixed the time of its meeting at St. Louis for September 15, 16, and 17; and this will be immediately followed by the sessions of the various medical departments of the Congress of Arts and Sciences, beginning September 19.

Will Seek Germ of Scarlet Fever among the Simian Tribe.—It is reported that Dr. Ludwig Hektoen, head of the Memorial Institute for Infectious Diseases, will go to Europe about April 1, for the purpose of making extensive experiments on apes, in the hope of finding the scarlet fever germ. He will undertake the trip because of the difficulty and expense of bringing the animals to this country.

Academy of Medicine.—The twenty-ninth annual meeting of the American Academy of Medicine will be held at the Shelburne, Atlantic City, beginning on Saturday, June 4, at 11 a. m., and continuing through Monday the sixth. Among other things the program includes the report of the committee to investigate the teaching of hygiene in our public schools. In order that this report may be discussed intelligently, the committee will publish the laws relating to the teaching of hygiene now in force in the United States, in the Bulletin of the American Academy of Medicine, to be published in April, 1904. It is believed this is the most complete and accurate compilation of these laws published, and the only compilation issued in an easily accessible and low priced publication. (Any number of the Bulletin will be sent to any address upon receipt of 50 cents.)

Professor Paul Ehrlich Visits the United States.—The visit of Professor Ehrlich, who, on April 1, read a paper before the association of pathologists and bacteriologists in Baltimore, is an event of marked interest in scientific circles. Professor Ehrlich, though still in middle life, has been for years one of the foremost figures in medical research. His visit to this country is to deliver, at the Johns Hopkins University, the Herter lectures for this year, the lectures having been founded by Dr. Charles Herter, of New York City. Since 1896 Professor Ehrlich has been director of the Institute of Serum-Therapy at Frankfurt-on-the-Main, where the German government maintains a splendidly equipped laboratory. He has a staff of assistants, and the German government spends \$16,000 annually for the expense incurred by Professor Ehrlich's laboratory. He is allowed to pursue original investigations in any field which he sees fit. The only provision in this country for original research that at all resembles Professor Ehrlich's laboratory which is sustained by the German government, is the Carnegie Fund; and the Rockefeller Institute lately established in New York.

Miscellaneous.—**Cambridge, Mass.:** Professor H. C. Ernst, of the Harvard Medical School, has recently appeared before a committee of the Massachusetts Legislature, in opposition to the bill to restrict animal experimentation in the State. At a meeting of the Massachusetts Medical Society, March 23, the section for obstetrics and diseases of women elected Daniel H. Craig president.—**New York:** The resignation of Dr. Frederick W. Peterson, as president and member of the New York State Commission in Lunacy, has been announced. Professor Frederic S. Lee, who has recently been promoted to a full professorship of physiology at Columbia University, has been granted leave of absence for the academic year of 1904-05, and will spend the time in European laboratories.—**North Carolina:** Dr. R. O. E. Davis, instructor in chemistry in the University of North Carolina, having been granted a year's leave of absence, sails on April 16 for work in the laboratories of Professors Ostwald and van't Hoff.—**Philadelphia:** The new medical laboratories of the University of Pennsylvania will be dedicated on June 11. The laboratories cost \$700,000. The principal addresses will be delivered by Dr. H. P. Bowditch, professor of physiology at the Harvard Medical School; Dr. R. H. Chittenden, director of the Sheffield Scientific School, Yale University; Dr. George Dock, professor of medicine at the University of Michigan, and Dr. Horatio C. Wood, professor of materia medica and pharmacy at the University of Pennsylvania.—**St. Paul, Minn.:** Dr. Jacob E. Schadle has been appointed professor of rhinology and laryngology in the College of Medicine and Surgery of the University of Minnesota, to succeed Dr. Laton, resigned.—**Foreign:** The Turin Academy of Science has awarded one-half of the Vallauri prize of \$6,000 to Professor Giovanni Battista Grassi, of Rome, in recognition of the value of his researches on malaria.—**The Russian Government** has offered a prize of about \$25,000 for the discovery of some method to make alcohol undrinkable.—**Germany:** The number of medical students in Germany has decreased 22% in the last decade.

Organizations for the Study of Tuberculosis in This Country.—For the purpose of discussing the question, the following met at the College of Physicians, Philadelphia, on the afternoon of March 28: Howard S. Anders, Philadelphia; J. M. Anders, Philadelphia; Wm. M. Angney, Philadelphia; Henry G. Beyer, United States Navy; Herman M. Biggs, New York; Jno. J. Black, New Castle, Del.; Oliver A. Blumenthal, Syracuse, N. Y.; Vincent Y. Bowditch, Boston; M. J. Brooks, New Canaan, Conn.; Herbert C. Clapp, Boston; L. Solis Cohen, Philadelphia; Solomon Solis Cohen, Philadelphia; W. M. L. Coplin, Philadelphia; Frank A. Craig, Philadelphia; Alex. H. Davison, Philadelphia; B. H. Detweiler, Williamsport, Pa.; A. H. Doty, New York; J. W. Ellenberger, Harrisburg; W. B. Fetterman, Jr., Philadelphia; Lawrence F. Flick, Philadelphia; F. Forchheimer, Cincinnati; Albert C. Getchell, Worcester, Mass.; William B. Hackenbourg, Philadelphia; H. A. Hare, Philadelphia; Charles J. Hatfield, Philadelphia; Henry D. Holton, Brattleboro, Vt.; A. Jacobi, New York; Henry Barton Jacobs, Baltimore; Edward G. Janeway, New York; Herbert M. King, Liberty, N. Y.; S. A. Knopf, New York; Alexander Lambert, New York; H. R. M. Landis, Philadelphia; Charles M. Lewis, Philadelphia; Daniel Lewis, New York; D. J. McCarthy, Philadelphia; James Alex. Miller, New York; Charles H. Miner, Wilkesbarre, Pa.; Charles H. Minor, Asheville, N. C.; J. H. Musser, Philadelphia; Estes Nichols, Augusta, Me.; George W. Norris, Philadelphia; William Osler, Baltimore; Jay Perkins, Providence; W. H. Peters, Providence; C. O. Probst, Columbus, Ohio; John H. Pryor, Ray Brook, N. Y.; Mazzyck P. Ravenel, Philadelphia; DeLancey Rochester, Buffalo; Milton J. Rosenau, Washington; J. T. Rothrock, Mont Alto, Pa.; W. B. Stanton, Philadelphia; George M. Sternberg, Washington; Elwell Stockdale, White Haven, Pa.; Arthur K. Stone, Boston; J. Edward Stubbert, New York; J. M. Taylor, Boise, Idaho; James Tyson, Philadelphia; T. Mellor Tyson, Philadelphia; Josephus T. Ullen, Germantown, Pa.; Agnes C. Vietor, Boston; Joseph Walsh, Philadelphia; Samuel B. Ward, Albany; William H. Welch, Baltimore; J. M. Willcox, Philadelphia; Francis H. Williams, Boston; J. C. Wilson, Philadelphia. Professor William Osler, of Baltimore, presided, and Dr. Henry Barton Jacobs, of Baltimore, acted as secretary. After a full discussion participated in by Doctors Daniel Lewis, Minor, Flick, Knopf, Solomon Solis Cohen, James Tyson, Stubbert, Pryor, Holton, Biggs, Rothrock, Jacobi, Janeway, Hare, Sternberg, Welch, Forchheimer, Ravenel, Rochester, and Ward, Dr. Lawrence F. Flick, of Philadelphia, offered the following resolution, which was seconded by Dr. Forchheimer, and carried unanimously: *Resolved*, "That we here assembled do now organize ourselves into a United States Society for the Study of Tuberculosis." It was then moved by Dr. George M. Sternberg, of Washington, and seconded by Dr. Hare, of Philadelphia, "that the chair appoint a committee of five to prepare a constitution and by-laws for such a society." This motion was carried unanimously. The chair appointed Dr. Edward L. Trudeau, Dr. Herman M. Biggs, Dr. Lawrence F. Flick, Dr. William H. Welch, and Dr. George M. Sternberg as that committee. It was further moved by Dr. Sternberg, and carried unanimously, "that the chairman and secretary of this meeting be ex officio chairman and secretary of the committee." Dr. Ravenel then moved, and it was unanimously carried, "that it is the sense of this meeting that the committee call us together for organization, at Atlantic City, during the week of the meeting of the American Medical Association."

NEW YORK.

The Medical Society of the State of New York has issued a circular letter to the officers of the County Medical Societies of that State, which is as follows: Action has been taken for consolidation of the medical profession of the State by both the State bodies. The committee thereon deems it advisable to take the necessary legal steps before the Supreme Court in May. Before doing this it is important that every county society shall take action upon the ratification resolutions, which were sent to you in February. Less than half of the societies have acted. We urge you, therefore, to secure a special meeting of your society during April, getting a quorum at least together after due notice to all members, and to act in this matter, using the form of resolutions which has been sent to you. All are interested in having no obstacle in the way of perfecting this unification, and we hope you will secure speedily this action by your society.

The Need of a Municipal Tuberculosis Sanatorium.—Arguments for the erection of a municipal sanatorium for the care of the tuberculous of New York City is advocated in *Charities*. The mere statement that the existing hospitals and sanatoriums to which patients may be sent can accommodate not more than 1 out of every 20 persons in the tenements who are suffering from tuberculosis would seem to be sufficient to establish the imperative need of further provision. It follows from this premise that the other 19 out of every 20 must remain in their tenement homes; the advanced cases to spread infection; the earlier cases, which might, and therefore should, get well, to grow worse and die. For the New York tenement, at its best, can hardly be transformed into an ideal sanatorium; and the patient who is one of a family of 5 living in 3 small rooms must be most intelligent and most conscientious to avoid

endangering the rest of the family. Private relief agencies can, and do, to an increasing degree, mitigate the unfavorable surroundings, but they realize, probably more keenly than do others, the suffering that might be prevented if there were a suitable place to send every poor tuberculous patient who is willing to go to a sanatorium. The number of persons in the city who would benefit by sanatorium treatment is not, of course, equivalent to the effectual demand for sanatorium treatment, since there are many who cannot be persuaded to leave home. The history of the Tuberculosis Infirmary on Blackwell's Island is convincing evidence of an increasing willingness on the part of the poor of the city to avail themselves of the facilities at their disposal.

School Children Utilized by the Health Board in the Educational Campaign against Tuberculosis.—A New York exchange says: In an attempt to check the dissemination of pneumonia and germs of other diseases of the respiratory organs, President Darlington, of the Board of Health, has enlisted the aid of half a million school children. His idea is that they will not only help greatly in the enforcement of laws prohibiting expectoration on sidewalks and in public conveyances, but that, in educating the child he will be educating the man. Great quantities of slips are being printed by the Department of Health for distribution among the children, and at the same time the teachers will be expected to explain the seriousness of the dangers involved in the practice of spitting in public places. It is designed that both boys and girls carry a little pad of the warning slips, and that when they see a man violating the ordinance they will hand him a card warning him of the heavy fine to which he is liable. Public school teachers also will be directed to take particular pains in pointing out to their charges the dangers of violations of the sanitary code.

PHILADELPHIA, PENNSYLVANIA, ETC.

Lectures on Tropical Diseases.—Since somewhat more than a year ago, when Captain Charles Keiffer delivered, in Philadelphia, the first series of lectures on the subject of tropical diseases at the Jefferson Medical College, the subject has assumed increased importance. At present the medical department of the University of Pennsylvania has provided for a similar course, and Major Guy L. Edie will deliver a course of 10 lectures on this subject, beginning Wednesday, March 23. Medical students and physicians in the city are invited to be present.

The Henry Phipps Institute.—The anniversary dinner was given by the staff of the University Club on March 28. The delegates to the convention, which was called to consider the question of forming a national organization for the study of tuberculosis, were all invited as guests of the occasion. Sixty-two persons were present, among whom were many of the most eminent physicians of the United States. The feature of the evening was the presentation of a silver pitcher to Dr. Lawrence F. Flick, the director of the Henry Phipps Institute, by the members of the Staff. The founder of the institute was present, and made the presentation in the name of the staff.

Morbidity and Mortality in Philadelphia.—Physicians report that a rare form of grip has made its appearance in the city. Its most predominant symptom has reference to the brain and nervous system. It closely resembles cerebrospinal meningitis, with the exception of the unconsciousness, and runs for a period of 3 or 4 weeks. During the week ended March 26 there were 88 new cases of diphtheria, as compared with 67 during the previous week; 116 new cases of scarlet fever, as compared with 101 of the previous week; 148 cases of typhoid fever, as compared with 141 of the previous week; and 35 cases of smallpox, as compared with 30 cases during the previous week.

Physical Examination of Would-be School Teachers.—The Board of Education proposes to institute a standard of physical qualification of applicants for admission to the Normal School or the School of Pedagogy and of all other applicants for certificates of qualification to teach in the schools. Similar health standards have already been adopted in other cities. The proposed rule sets forth that all such applicants shall be required to furnish a certificate of physical fitness in accordance with prescribed forms, to be signed by a physician. The fourth section of the proposed rule reads: "No person who shall be certified as having phthisis, any contagious disease of the skin or mucous membrane, or any defect in hearing or in sight which will probably disqualify him or her from efficiently performing the duties of a teacher shall be admitted to the Normal School or School of Pedagogy or be permitted to attend any examination of applicants for certificates of qualification to teach in the Philadelphia schools. Nor shall any such person receive a certificate of qualification to teach upon completion of the course of study prescribed for the Normal School or the School of Pedagogy. If, however, the disease or physical defect which disqualifies the applicant shall not be incurable, the person temporarily disqualified shall, upon a certificate from the physician that the disqualifying cause no longer exists, be eligible for admission to the Normal School or the School of Pedagogy, or to receive the certificate of qualification which he or she has earned at either of said schools."

Schuylkill County Insane Asylum Unfit for Use.—Dr. George I. McLeod, secretary of the State Lunacy Commission, sustains the diverse criticism of a grand jury, which recently viewed Schuylkill County Insane Asylum, and is quoted as saying: The buildings are old, dilapidated, and overcrowded. They are in such a condition as to render them totally unfit for occupancy. The laws of sanitation are violated in several ways, and as many as 8 men are compelled to occupy a room 9 by 16 feet. I think the conditions are a disgrace to Schuylkill county. They are worse than any in this State of which I have knowledge. The accommodations are such that the authorities have refused to take in any more patients, but when they are sent there by order of the Court, it is obligatory to accept them. Thus conditions are becoming worse. The house and bedding are clean, but this is not all that is needed in a well-regulated hospital for the insane.

To Enforce Vaccination.—An exchange states that a bill will be introduced into the next Legislature giving the Department of Health power to enforce vaccination. Pennsylvania's only Compulsory Vaccination law applies exclusively to children and prohibits their attendance in any public, parochial, private or Sunday schools unless they have been successfully vaccinated. In the case of cities of the second and third class there are partial compulsory vaccination acts which may be enforced by the Boards of Health. It is enacted that in cities of the second class (Pittsburg) the Bureau of Health may, when it shall be deemed necessary to prevent the spread of smallpox, issue an order requiring all persons in the city to be vaccinated. Failure to comply with such order subjects offenders to a fine of not less than \$5 nor more than \$25. Similarly, as amended May 16, 1901, the act of May 23, 1889, providing for the incorporation of cities of the third class, empowers the Boards of Health of such cities to enforce vaccination and to make and enforce all needful rules and regulations to prevent the introduction and spread of infectious and contagious diseases.

Filters Will Lower Typhoid Rate.—The Bureau of Health of Philadelphia is sanguine that the installation of the filter plant now under course of construction will very materially reduce the mortality from typhoid fever in the city. Chief Hill of the filtration bureau assumes that the mortality will be reduced 80%. In confirmation of this view he states the number of cases of typhoid fever in the twenty-first and twenty-second wards, where filtered water is now being used, as compared with the rest of the city which is using unfiltered water. In the section using filtered water the average weekly morbidity from typhoid fever for 11 weeks beginning January 1 and ending March 18 was 3.73 per 100,000 of population, whereas in that portion using unfiltered water the morbidity was 10.46 per 100,000 of population. As showing the further pollution of the Schuylkill River water as compared with the Delaware River water, the morbidity in the section supplied by Schuylkill River water for the same period of 11 weeks, was 13.82, and in the section supplied by Delaware River water it was 11.53 per 100,000 of population.

SOUTHERN STATES.

A Cantata: Hygeia.—At the second public concert of the Washington Saengerbund, held Sunday evening, March 20, 1904, a noteworthy feature of the occasion was the rendition of a cantata, "Hygeia," composed by Dr. John C. Hemmeter, of Baltimore, and dedicated to Professor W. H. Welch of Johns Hopkins Medical College.

Maryland Tuberculosis Bill Reconsidered.—The failure of the tuberculosis bill recently to pass the Senate in the Maryland Legislature was a distinct disappointment to the friends of that measure in the city. The reason assigned by the opponents of the bill was that the information to be secured by the appointment of a commission and the appropriation of \$2,000, for investigating the subject, could be obtained from the medical colleges of the city without such commission and appropriation. It appears, however, that the friends of the measure came to the rescue in time and on the presentation of a strong plea by Drs. Osler, Fulton, Young and others the Senate was induced to reconsider the measure. It was made plain by the physicians named that the work of the commission cannot be carried out by the medical schools.

WESTERN STATES.

Antitoxin and Diphtheria in Chicago.—The experience of Chicago's Health Department in 7,435 cases of diphtheria shows that the mortality when antitoxin is used is 6.5%. The mortality without antitoxin is still about 35%.

Sealed Milk Cans in Chicago.—A proposed ordinance provides that all milk cans must be sealed by the proper shipper before he delivers them to the railroad, and a fine of from \$10 to \$100 is provided for the Chicago dealer who receives a can which is not sealed or the seal of which is broken. The object is to locate the responsibility for impure milk. When the health department now finds bad milk the dealer blames the farmer who shipped it, and the farmer in turn accuses the railroad men of tampering with it while in their charge. They charge that railroad men often take milk from cans and fill them with water.

FOREIGN NEWS AND NOTES

GENERAL.

Fighting Yellow Fever at Guayaquil.—Information from Guayaquil, March 25, says: An active campaign against the spread of yellow fever and malaria, involving the destruction of mosquitos, has been started here as the result of suggestions of Dr. Gruver, the resident officer of the United States Marine-Hospital Service. The municipality is printing thousands of pamphlets for general distribution, embodying the regulations of the United States Marine-Hospital Service for the prevention of the spread of yellow fever.

OBITUARIES.

David Mackay, surgeon-general of the National Organization of the G. A. R., at his home in Dallas, Texas, March 23, aged 72; a native of Glasgow, Scotland. He served in the Crimean war, later settled in New York where in 1881 he enlisted in the Seventh and Ninety-fifth New York Volunteers and served as surgeon throughout the war. He was physician to the city of New Orleans and surgeon of the Marine Hospital in that city from 1866 until 1870.

Amos Seip, at his home in Easton, Pa., March 21, aged 81; a graduate of the University of Pennsylvania in 1848. He had practised medicine for more than a half century. Three years ago a stroke of paralysis caused him to retire from active practice. He attained prominence during the cholera epidemic in Lehigh county in 1855 and was in charge of a soldier's hospital at Easton, Pa., during the Civil war.

Dr. Francisco de P. Chacon, at his home in Mexico City, February 9. He was professor of the chair of surgical anatomy in the Mexican National School of Medicine in Mexico City and had been for many years, one of the most prominent figures in the medical profession of Mexico. A contemporary says that "the history of his labors will be the history of the progress of medicine in Mexico."

John D. Young, at his home in Winthrop, Mass., March 25, aged 63; a graduate of the Pennsylvania Medical University in 1864 and of the Eclectic Medical College of Massachusetts. He was prominent among Odd Fellows and Masons of which organizations he was a member.

Alfred Duperier, at his home in New Iberia, La., March 24, aged 80; a graduate of the University of Michigan. He was prominent in political affairs during the Civil war and rendered effective service in the yellow fever epidemics of 1853 and 1857 in southwest Louisiana.

James S. McCorkle, at his home in Newbern, Tenn., March 11, aged 66; a graduate of the University of Nashville, in 1861. He served several terms as mayor of Newbern, was a Confederate veteran and for many years president of the local Board of Education.

William Gulick, of pneumonia, at his home in Watkins, N. Y., March 16, aged 90; a graduate of the College of Physicians and Surgeons of the Western District of New York, in 1837; one time president of the State Board of Health of New York.

Frank K. Irving, at the City Hospital, Newark, N. J., March 19, aged 35. It was asserted that he died from tuberculosis to which he had subjected himself in his search for a means of curing that malady by reaching the germs with an electric current.

Nathaniel T. Palmer, at his home in Brunswick, Maine, March 18, aged 87; a graduate of the Medical School of Maine, Brunswick. He was one of the founders of the American Medical Association and practised in Brunswick for nearly 60 years.

Hans Hermann Behr, at his home in San Francisco, March 13, aged 85; a graduate of the University of Berlin in 1843. He was the vice-president and curator of the San Francisco Academy of Scientists in 1864 and a well-known scientist.

Spottswood W. Carmichael, at his home in Fredericksburg, Va., March 18, aged 73; a graduate of the Jefferson Medical College, Philadelphia, in 1852 and a surgeon in the Confederate service during the Civil war.

G. Henry Chebot, from a complication of diseases, at his home in Baltimore, March 24, aged 43. He was a native of Baltimore and a member of the Medical and Chirurgical Society and the Shield of Honor.

M. Thomas Brennan, from pneumonia, at his home in Montreal, March 12, aged 42; a graduate of the Laval University, Quebec, in 1884. He was gynecologist to Notre Dame Hospital, Montreal.

John Edward Janney, from an overdose of chloroform which was mistaken for whisky, at his home in Winchester, Va., March 20, aged 50; a graduate of the University of Virginia in 1874.

John Marion Watkins, at his home in Opelika, Ala., March 12, aged 60; a graduate of Tulane University, New Orleans, in 1871 and a member of the American Medical Association.

R. Edgar Zakery, after an operation for appendicitis at the James Walker Memorial Hospital, Wilmington, N. C., March 12; a graduate of the University of North Carolina, in 1898.

William O. Osgood, at his home in Chicago, March 20. During the Civil war he was lieutenant-colonel of the Seventh Kansas Cavalry. He resided in Chicago nearly forty years.

Josiah S. Duff, aged 49, March 22, suddenly as result of swallowing a dose of carbollic acid which he mistook for essence of pepsin. Aid was hurriedly called but proved futile.

Thomas E. Moore, at his home in Bolivar, Tenn., March 10, aged 86; a graduate of Transylvania University, Lexington, Ky., in 1841.

Leander Swartwout, at his home in Prospect, N. Y., March 11, aged 61; a graduate of the Albany Medical College in 1880.

Edward P. Woodward, at his home in Bristol, Conn., March 23, aged 67; a graduate of the Yale Medical School in 1860.

Lawrence L. Glover, at his home in Haddonfield, N. J., March 25; a graduate of Jefferson Medical College in 1882.

William Moseby Mercer, at the home of his son in Baltimore, March 24, aged 76.

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended March 25, 1904:

Changes in the Medical Corps of the U. S. Navy for the week ended March 26, 1904:

GREEN, E. M., medical inspector, detached from the Kentucky and ordered to the New Orleans—March 21.

FITZSIMONS, PAUL, medical director, ordered to Navy Yard, Washington, D.C.—March 21.

BISHOP, L. W., assistant surgeon, detached from the Annapolis and ordered to Naval Hospital, Mare Island, California, for treatment—March 21.

MUNSON, F. M., assistant surgeon, detached from the Frolic and ordered to Naval Station, Pollok, P. I.—March 21.

TRAYNOR, J. P., assistant surgeon, detached from the Naval Station, Pollok, P. I., and ordered to the Frolic—March 21.

MCCLANAHAN, R. K., assistant surgeon, ordered home and granted sick leave for three months—March 21.

LEDBETTER, R. E., assistant surgeon, detached from the Newark and ordered home to wait orders—March 21.

RENNIE, W. H., HOEN, W. S., VERNER, W. W., GRIEVE, C. C., DEBRULER, J. P., DEAN, F. W. S., DYKES, J. R., GEIGER, A. J., assistant surgeons, detached from the Naval Museum of Hygiene and Medical School, and ordered to the Asiatic Station, via Solace—March 21.

SCOTT, S. L., assistant surgeon, detached from the Naval Museum of Hygiene and Medical School, and ordered to the Massachusetts—March 21.

The following named medical officers, also, having been detached from the Naval Museum of Hygiene and Medical School, have received orders as follows: Assistant Surgeon B. H. Dorsey to the Illinois, Assistant Surgeon A. D. McLean to the Alabama, Assistant Surgeon J. D. Manchester to the Columbia, Assistant Surgeon C. E. Rider to the Missouri, Assistant Surgeon W. S. Pugh, Jr., to the Prairie, Assistant Surgeon T. N. Pease to the Hartford, Assistant Surgeon I. S. K. Reeves to the Minneapolis, Assistant Surgeon R. L. Sutton to the Bureau of Medicine and Surgery, Assistant Surgeon C. F. Ely to the Naval Academy, Assistant Surgeon P. T. Dessez to the Naval Academy, Assistant Surgeon J. S. Woodward to Indian Head Proving Ground, Assistant Surgeon E. E. Higgs to Newark, Assistant Surgeon W. B. Smith ordered to the Olympia, Assistant Surgeon F. G. Abeken to Training Station, San Francisco, Assistant Surgeon P. S. Rossiter to Baltimore Recruiting Station, Assistant Surgeon O. Kohlbase to the New York, Assistant Surgeon J. A. Randall ordered to the Maine—March 22.

PRYOR, J. C., passed assistant surgeon, detached from the Bancroft and ordered home to wait orders—March 22.

MCDONNOLD, P. E., assistant surgeon, detached from the Olympia and ordered home to wait orders—March 22.

PLUMMER, R. W., passed assistant surgeon, ordered from the Maine to the Bancroft—March 23.

Changes in the Public Health and Marine-Hospital Service for the week ended March 24, 1904:

CARTER, H. R., surgeon, to report at Bureau for special temporary duty—March 19, 1904.

PECKHAM, C. T., surgeon, detailed for duty on Revenue Cutter Service Retiring Board at New York, N. Y.—March 21, 1904.

SMITH, A. C., passed assistant surgeon, detailed for duty on Revenue Cutter Service Retiring Board at New York, N. Y.—March 21, 1904.

ROSENAU, M. J., passed assistant surgeon, to proceed to Boston, Mass.; Albany and New York, N. Y., for special temporary duty—March 22, 1904.

McMULLEN, JOHN, passed assistant surgeon, bureau order of February 29, 1904, directing Passed Assistant Surgeon John McMullen to report to chief quarantine officer of Hawaii for duty, revoked—March 22, 1904.

FOSTER, M. H., passed assistant surgeon, granted leave of absence for ten days from March 30—March 19, 1904.

LUMSDEN, L. L., passed assistant surgeon, relieved from duty at New Orleans, La., and directed to proceed to Vera Cruz, Mexico, for duty in office of the United States Consul—March 21, 1904.

KING, W. W., assistant surgeon, granted leave of absence for six days from March 18—March 19, 1904.

GOLDBERGER, JOSEPH, assistant surgeon, relieved from duty in Hygienic Laboratory, and directed to proceed to Tampico, Mexico, for duty in the office of the United States Consul—March 22, 1904.

ROBERTS, NORMAN, assistant surgeon, relieved from duty at San Diego, Cal., and directed to proceed to New Orleans, La., and report to medical officer in command for duty and assignment to quarters—March 23, 1904.

SALMON, T. W., assistant surgeon, relieved from duty at Philadelphia, Pa., and directed to proceed to New York, N. Y. (Stapleton), and report to medical officer in command for duty and assignment to quarters—March 18, 1904.

BAKES, E. C., acting assistant surgeon, granted leave of absence for three days from March 19, 1904, under paragraph 191 of the regulations—March 18, 1904.

MACRALL, B. McV., acting assistant surgeon, granted leave of absence for fifteen days from March 31—March 17, 1904.

TIDD, E. M., acting assistant surgeon, granted leave of absence for fourteen days from April 1—March 19, 1904.

Board Convened.

Board convened to meet at Washington, D. C., March 25, 1904, for the physical examination of an officer of the Revenue Cutter Service.—

Detail for the board: Assistant Surgeon-General L. L. Williams, chairman; Assistant Surgeon-General W. J. Petrus, recorder.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

GOVERNMENT INSPECTION OF ESTABLISHMENTS MANUFACTURING VIRUSES, SERUMS, TOXINS, ANTITOXINS, AND SIMILAR PRODUCTS.

BY

M. J. ROSENAU, M.D.,

of Washington, D. C.

Director of Hygienic Laboratory.

To the Editor of American Medicine:—In your issue of March 5 appears a letter from Dr. M. T. Naughton, of Chicago, in which he states that the United States Government does not require an inspection of establishments manufacturing viruses, serums, toxins, antitoxins, and similar products. I write this in order to correct the wrong impression in Dr. Naughton's mind as well as to give the medical profession an opportunity of knowing just what is being done along these lines.

On July 1, 1902, the President signed a law entitled "An act to regulate the sale of viruses, serums, toxins, and analogous products in the District of Columbia, to regulate interstate traffic in said articles, and for other purposes." This law is too long to quote verbatim, and I therefore give you some of its main features.

It first of all requires establishments, whether in the United States or foreign countries, manufacturing therapeutic serums, toxins, antitoxins or analogous products applicable to the prevention and cure of diseases of man, to hold an unsuspended and unrevoked Government license.

This law forbids, under penalty of a fine and imprisonment, the interstate traffic in any such product made in an illicit and unauthorized manner. It also requires that each package of such virus, serum, toxin, antitoxin, or similar product be plainly marked with the proper name of the article contained therein, and the name, address and license number of the manufacturer, as well as the date beyond which the contents cannot be expected beyond a reasonable doubt to yield results.

A fine not to exceed \$500, or imprisonment not to exceed one year, or both, in the discretion of the court, attaches to the person who shall alter or falsely label or mark any package or container of any virus, serum, toxin, antitoxin, etc.

The law further provides for the detail of an officer of the Public Health and Marine-Hospital Service (Treasury Department) to inspect establishments propagating these products for sale, barter or exchange from one State or Territory to another.

A board consisting of the Surgeon-General of the Army, the Surgeon-General of the Navy, and the Surgeon-General of the Public Health and Marine-Hospital Service, is provided by the law to promulgate such rules as may be necessary in their judgment to govern the issue, suspension, and revocation of licenses for the maintenance of these establishments. In accordance with this provision of law, regulations have been drawn up and approved February 21, 1903, covering in detail the form of license, which is good for only one year from the date of issue and is not reissued without another inspection.

The inspection of an establishment is made by an inspector or a board of inspectors detailed by the Secretary of the Treasury upon the recommendation of the Surgeon-General of the Public Health and Marine-Hospital Service. The report of this inspection is reviewed by the Sanitary Board and the Surgeon-General, and licenses are issued by the Secretary of the Treasury.

Licenses may be suspended or revoked for cause, such as faulty methods of manufacture, faulty construction, or administration of establishments; or if impurities or lack of potency of the products is demonstrated by the laboratory examination.

The director of the Hygienic Laboratory is charged with the examination of samples of vaccines, toxins, antitoxins, and similar products of all manufacturers holding a license in order

to see that they maintain their standard, and no establishment is given a license until samples of their products have been examined with this end in view in the Hygienic Laboratory.

It will be seen from the foregoing brief review of the law and its regulations that Congress has provided a complete system for governing the manufacture, sale of and interstate traffic in vaccine, serums, and antitoxins, in order to standardize dosage, control the technic, and give the physician who uses these products a reasonable assurance of their purity and potency.

I may state that since the enactment of this law, which has been in operation a little over one year, 4 establishments have been refused licenses and have therefore been compelled to go out of business, because the inspectors found they were manufacturing biologic products without due precautions to prevent contamination, or because they did not have competent scientists to test properly their vaccines and antitoxins in accordance with modern methods. Other manufacturers who were granted licenses were first required to improve their methods, rebuild their laboratories and barns, or otherwise change their system so as to insure a safe, pure and standard product.

The operation of the law has already resulted in a great improvement in the vaccines and antitoxins found on the market, and as the workings of the law, which is still comparatively new and evidently little known, become better known, further improvement may be expected.

The Hygienic Laboratory is now preparing a standard unit for diphtheria antitoxic serum for distribution to various manufacturing establishments, laboratories and original investigators especially interested in this subject. This unit is based upon that established by Ehrlich and will be maintained and distributed free of cost as the American standard.

THE AORTIC REFLEX.

BY

ALBERT ABRAMS, A.M., M.D.,
of San Francisco, Cal.

To the Editor of *American Medicine*.—The recent commendous though exhaustive article on "Thoracic Aneurysm," by Dr. Burt (*American Medicine*, February 2, 1904), emphasizes the difficulties besetting the clinician in the early diagnosis of this affection and confusion is further abetted in diagnosis in tortuosity of the aorta. What I have called the "aortic reflex" has been employed for some months in diagnosis. My reference to the reflex in question, at this time, is in the nature of a preliminary report, with the hope that others may determine its value either in a positive or negative direction. The manipulation of the vertebrae, by the osteopath, and the effects on the patient, are not wholly a question of suggestion; on the contrary, the osteopath unknowingly elicits many visceral reflexes which may operate for good or evil. Concussion of the spinous processes will induce palpable lung, heart, liver, stomach and intestinal reflexes, dependent on the vertebrae subject to concussion. To elicit dilation of the aorta, in a normal subject, I employ an S. S. White dental mallet, weighing about 4 oz., and a pleximeter of felt (Fig.). In the absence of the latter, a percussion hammer and a wide rubber cork may be used, although less effectively. Next, mark with a dermatograph the spinous processes of the eighth, ninth, tenth, eleventh and twelfth dorsal vertebrae, striking the latter through the pleximeter in rapid succession a series of sharp, vigorous blows. Immediately thereafter (for the reflex is of short duration, from a half to one minute), percuss with a strong percussion blow the region of the thoracic aorta and the course of that vessel may be defined. Concussion of the spine of the seventh cervical vertebra after the same manner causes the dulness to evanesce at once (the counterreflex of aortic contraction). That alternate dilation and contraction of the aorta follow the concussion maneuvers already mentioned, may be controlled by the röntgen rays. The course of the upper surface of the normal aorta (Fig. 2) in the adult of middle life may be projected on the thorax by drawing a

curved line, beginning at a point corresponding to the right sternal line in the middle of the first intercostal space and ending at the point of insertion of the first left rib to the sternum. The highest point of the aortic arch is distant about 5 cm., and the beginning 2 cm. from the anterior thoracic wall, hence a forcible percussion blow which is propagated to a depth of about 5 cm. cannot fail to elicit the dulness of the aortic arch if dilated. In a patient with aneurysm of the thoracic aorta, who was recently examined by Dr. J. B. Frankenhimer, of this city, and myself, the aortic reflexes were specially pronounced, and this, despite the fact that theory would have dictated otherwise, considering the suppositious annihilation of the vessel's elasticity. The interrupted lines are the areas of percussion dulness (Fig.) of the aneurysm: (1) before elicitation of the aortic reflexes; (2) after elicitation of

Fig. 2

Fig. 1.—Mallet and pleximeter for producing the aortic reflexes.

the reflex of dilation, and (3) after evoking the aortic reflex of contraction. Control investigations demonstrated that the lung was in no wise implicated in the percussion changes. The röntgen rays employed for control purposes failed to correspond in degree with the decided changes noted by percussion, and this was fully in accord with reason, considering the fact that while percussion adduced results varying with the approximation of the aneurysmal sac to the thoracic wall, with the rays, the sagittal diameter of the sac was not taken into account. The aortic reflexes are, in my experience, fairly constant, but variable in duration, and if the observations of others confirm my results, the reflexes in question may serve a useful purpose not only in diagnosis, but in treatment.

A DISCLAIMER.

It has just come to our notice that one J. Sills Daniels, M.D., of Roanoke, Va., the proprietor of a so-called Cancer-cure Sanitarium, and Sanitarium for the Treatment of Diseases of Women, especially obstetric cases, an asylum for the unfortunate, etc., who also offers a diploma as a member of the Hospital Staff, for a consideration to any physician desiring it, has without our knowledge or authority, announced us as consulting physicians of the said sanitarium. We desire to stamp such a statement as a piece of unwarranted impertinence, and absolutely without any foundation in truth.

FIFTEEN YEARS' EXPERIENCE WITH UTERINE FIBROIDS.

BY

WILLIS E. FORD, M.D.,

of Utica, N. Y.

Fellow American Gynecological Society; Gynecologist St. Luke's Hospital, Utica, N. Y.

The methods of dealing with fibroid tumors of the uterus are so thoroughly agreed upon by the profession of this day, and the methods of operating for their removal have become so perfected that there is but little disagreement as to what is best to do for a woman who has a fibroid. Such was not the case, however, even a few years ago, and those of us who have lived long enough to hear the question discussed as to whether an operation was justifiable or not, and what operation was attended with the least mortality, and what the ultimate results of these various procedures have been, marvel at the accounts written 15 years ago by the very best men in our profession. I have had in mind for a long time the idea of collecting my own cases of fibroid tumors, especially for the purpose of giving the after-history of the patients, whether treated by the conservative or tentative method or by radical means. While I have been working on this for some time I have found it a very difficult thing to do, and I finally excluded all the cases in my private practice and am able to present only part of the cases that have occurred in my services at St. Luke's Hospital during the past 15 years. The number is not large enough to draw many definite conclusions from, and I shall make no attempt to do this; but the fact that I have been able to follow the history of so many patients after they have left the hospital, and to know of their condition years later, has seemed to me a matter worth recording.

My impression is, that there was a greater number of fibroid tumors of the uterus 15 years ago than at the present time—just as there were many more cases of ovarian tumors in the community 25 years ago than at the present day. Both kinds of tumors had been neglected for so many years that there was what might be called an accumulation of cases. There are now so many excellent operators throughout the country who remove these growths when they are comparatively small that the very large ones are seldom found.

In 1888 I was an enthusiastic believer in the treatment of these tumors by means of electricity, and it is fair to say, that I discovered very early that those fibroids that had a pedicle and those that were called subserous growths were affected but little, or not at all, by electricity, and that, therefore, the patients I actually treated had cases of the intramural variety. While I had done some abdominal surgery, and occasionally had found a fibrocyst or a suppurating fibroid which I had mistaken for an ovarian tumor and had attempted an operation for its removal, I had not done up to this time a deliberate operation for a solid fibroid by abdominal section. It is true, that as far back as 1884 the question of the removal of fibroid tumors by abdominal section was engaging the attention of a few men, especially Tait, Keith, Bantock, and Martin, but the operation was not looked upon with favor by any considerable number on this side of the Atlantic. In 1884 Dr. Stanbury Sutton read a paper before the American Gynecological Society upon this subject.¹ In this paper he enthusiastically advocated the extirpation of these growths by surgical procedure. He had recently returned from abroad, where he had witnessed these operations in the hands of the masters of the profession, and was convinced that it was the coming method. The operation at that time was done by bringing the stump of the amputated uterus out of the wound and fixing it,

generally with a *serre-nœud* or some variety of clamp, known as the extraperitoneal method. The other procedure for the relief of fibroids was oophorectomy, with the idea of stopping the growth of the tumor; or in the submucous varieties the evulsion of the tumor from its bed and its delivery through the vagina.

In 1887, Bantock, of London, read a paper before the American Gynecological Society in New York,² and in the discussion, such men as Martin, of Berlin, and Simpson, of Edinburgh, took part. The methods of operating were extraperitoneal mainly, and he reported 57 cases of his own, with 12 deaths by supravaginal hysterectomy and by the extraperitoneal method. It is not strange when so few men were operating for the removal of fibroids with such a high deathrate, that Keith, of Edinburgh, said that the method of operating must be so improved that the deathrate from operation would be less than the deathrate caused by fibroids that were left unmolested, before the operation could be justified. It is not strange, therefore, that those of us who at that time had a limited experience in abdominal surgery, and that mainly for the removal of ovarian tumors, tried every method other than abdominal section for the treatment and cure of these growths. In 1884, Keith³ advocated electricity vigorously, and the lesser operation of removing the ovaries. I quote from page 430. "The ultimate result of the complete removal of the ovaries in small tumors is extremely beneficial. The symptoms are cured, the growth is arrested, and in a considerable number of cases the uterus gradually returns to its natural size."

I have just glanced at the attitude of the medical profession at that time regarding these growths in order to explain why I was so zealous in the use of electricity for a number of years subsequent to 1888, for at this time, as shown in the repeated discussions on this subject by such men as Emmet, Lusk, Thomas, and Wilson, a reluctant assent was given to the operation, as is shown by the "Transactions of the American Gynecological Society" in 1884, 1886, 1887, 1892, and 1893. Dr. Seth Gordon, of Portland, Maine, one of the most successful abdominal surgeons, and at that early time an enthusiastic advocate of the method of treating these tumors by operation, made the following statement as late as 1893.⁴ "One year ago I read a short paper before the American Medical Association (Section on Obstetrics and Diseases of Women), in which I claimed that hysterectomy for uterine fibroids is the only proper conservative surgery, and that it can be made equally safe with that of ovariectomy at the present day. In the course of the discussion I found but 1 or 2 who were favorable to this presentation of the case, while the general tenor of the arguments was that only in a comparatively few cases were such radical measures justifiable, inasmuch as the mortality and suffering were so very insignificant when the cases are left to run their course." The most notable papers to my mind that were presented on this subject, either before or since that time, were read in 1892 before the American Gynecological Society by Dr. William M. Polk and Dr. Baer. The former advocated total hysterectomy, and the latter advocated what he called the "new method" (as it practically was) by supravaginal amputation, after tying off the broad ligaments and the uterine arteries—the operation which is today the most popular in the hands of all operators. Since that time American operators have been generally agreed that the proper treatment of fibroids which give symptoms is hysterectomy or myomectomy.

While I had done a few operations by the extraperitoneal method previous to 1884, it was in January of that year that I did my first operation by Baer's method, which I have steadily adhered to in all operations of this kind since. The whole number of patients with fibroid tumors whom I have treated at St. Luke's hospital since 1888 for a sufficient length of time to enable me to say that they were under treatment long enough

to get a definite result, and whose subsequent histories I have been able to ascertain, is 162. Of these, 114 were married, 37 were single, and 11 were widows. One was under 20 years of age, 13 were between 20 and 30, 56 were between 30 and 40, 57 were between 40 and 50, 24 were between 50 and 60, and 8 were between 60 and 70. Of this number 96 were treated by galvanism, most of them during the early years of my experience. It is fair to say that the treatment by Apostoli's method I had witnessed in his clinic, and that the current I used was a 6-ampere, 40-volt current, with the milliamperemeter in circuit registering from 50 to 100 milliamperes. Seven of these patients recovered as indicated by the disappearance of the symptoms and the tumor. Twenty-six were improved as to the symptoms of hemorrhage, pain, etc., so as to be able to resume their duties in life. Some few of this class suffered relapse and after a year or two were treated again in the same manner, and then remained well for a period of 5 years at least afterward.

The next class of cases, and by far the most important, numbers 25 patients whose histories I have been able to follow for at least 5 years subsequent to their treatment, and who were improved, as indicated by the facts that the tumor was smaller and continued to diminish in size after treatment was discontinued, and who remained in good health and were able to do their work. I could add materially to this list from my private practice. Six were unimproved in any particular. One patient died as the direct result of infection. The cause of death in this one case was due to the lighting up of an acute inflammation in an old gonorrheal salpingitis, which in those early years I did not have the skill to diagnose, and which produced a rapid sepsis. This is the only instance of accident or injury of a serious nature that has occurred to me in my use of this very heavy current of electricity. During that time when the discussion as to the treatment of these tumors by surgical means was hottest, and along about 1890 to 1895, it was charged by many who advocated operative procedure and who were skilled operators, that electricity had done harm in a number of the cases in which they operated afterward, and had lessened the chances of recovery by operation. I was not so well qualified to speak at that time on this question as I am now, but my impression was that the changes found in the tumors operated, and which were attributed to the deleterious influences of electricity, were not due to the current, but were caused either by an infection from its improper use or to the degenerative changes in the ovaries, tubes, or the tumor itself, which we now know to be most common in patients who have had no treatment until the operation for the removal. I still have this opinion, and while I now practise the operative treatment of fibroids, I cannot condemn the use of electricity on these grounds.

In the next group of 31 cases the patients were treated by curetment by tying the uterine arteries by vagina, and the medicinal treatment by ergot, thyroid extract, etc. Of these, 24 were temporarily improved, and 7 were unimproved, though in the improved cases the tumors were not appreciably diminished in size. I have grouped together the cases thus treated by various means, because I consider that one method is not much more important than another—or, at least, the results obtained were about the same, though, of course, the same method was not applicable for all cases.

The use of the curet in hemorrhagic cases gives temporary relief, providing the operation is carefully done. It is a safe procedure if carefully performed, but might prove a great danger unless the cases were carefully selected. I have seen a sloughing fibroid after a miscarriage, in which a curet had been vigorously used, and I thought with great harm. The hemorrhage comes from a diseased endometrium in these cases oftener than from a split capsule and hemorrhage from the tumor direct. I would not use the curet if I found

the tumor projecting into the cavity and its capsule ruptured. I do not think that ergot ever starved out a fibroid tumor so that it could be said to be of any permanent help. It is true that in a few cases in which the tumor is intramural and has a tendency to force its way into the cavity of the uterus, a long use of ergot aids this process so that a small tumor is thus forced forward and may be caught and removed through the dilated uterine canal. It seems to me, however, that this is the limit of the use in the administration of ergot.

So far as the theory of tying off the uterine arteries for the purpose of starving the tumor is concerned, my own experience is that the operation, which I tried faithfully in a few cases, was not fortunate. In the first place, it is a very difficult thing to catch the uterine arteries by vagina, especially if the tumor is low down. I abandoned it soon as a useless process, and one that was hazardous and difficult. Regarding the use of thyroid extract, I am in doubt now as to whether I got any permanent results or not. I do not think it lessened the hemorrhage in any considerable number of cases. I have been able to stop the bleeding lately by the use of adrenalin or the extract of suprarenal capsule, and I am quite positive that this animal extract has a decided influence in checking uterine hemorrhage, though none of these things has any special bearing on the cure of the tumor. As for other medicines, I cannot say positively that I have had any results worth reporting, though I have tried various things.

The number of patients operated upon is 61. Six of these were my early operations by abdominal section, with external treatment of the stump. Two of these died. It is fair to say that in one case the operation itself could not be wholly blamed, because the woman had an apoplexy a few days afterward, and I then learned that she had had a cerebral hemorrhage several years before, though I did not know this at the time of the operation. The other was a very large tumor in a woman who had been operated on before in New York for the removal of the ovaries, and the fibroid was sloughing, and death was caused by sepsis. Since that time all abdominal operations have been done by supravaginal amputation, after Baer's method. These numbered 34, with 4 deaths. By vaginal hysterectomy I have removed 10, with 1 death. These cases were attempted for tumors of considerable size, and soon after the reading of Jacob's paper in this country, and after I had seen him operate in Brussels, and Segon and Richellot, in Paris, for very large fibroids, by morcellement. I think too much was expected from this operation, and the American method by abdominal section proved to be safer. The 1 death was due to hemorrhage. Eleven patients were operated upon by dilation of the uterus and the enucleation of the tumor. Two of the tumors were very large, the others being small in size—that is to say, not larger, perhaps, than an orange. My experience with the operation, however, was not satisfactory, excepting in women who had borne children and had a large, short vagina, and in whom the tumor could be easily mapped out by the finger after dilating the uterus. Of course, I do not refer to the polypoid growths protruding into the vagina and held by a pedicle. It was harder to perform than abdominal section, and I think more dangerous. In 1 case I got a very large tumor detached and could not deliver it, and the hemorrhage was so profuse that I had to tampon the entire cavity and wait until the next day, when by slitting the cervix extensively I was able to deliver the tumor with forceps. I had no deaths from this procedure.

The number of patients operated upon out of the whole number shows a larger ratio than is normal. These cases were selected from a larger number seen in private practice and sent to the hospital for treatment. It is generally conceded that the majority of fibroids do not need treatment and that radical operation is demanded only when there are well-marked symptoms

due to pressure, hemorrhage, etc., or some peculiarity of the growth which threatens life. I think the following statement by Dr. Barton Cooke Hirst fairly represents the attitude of the best men in the profession today.⁵

"There is no excuse for dogmatism, prejudice, or self-interest in deciding this important question. A conscientious surgeon who carefully considers the interests of the patient alone, will probably not operate in much more than 20% of his cases. Malignant degeneration, telangiectasis, cystic degeneration, and necrosis are positive indications, but, as Olshausen points out, all these dangerous degenerations together do not affect more than 5% of all cases. A bleeding that is reducing the woman to invalidism or endangers her life, and that is not controlled by palliative treatment, indicates an operation. Impaction of the tumor in the pelvis, with pressure symptoms in the bowels and urinary tract, may demand operation. A steady growth which promises the attainment of great size by the tumor indicates an operation before the bulk of the growth becomes excessive."

The complications of fibroid tumors are seen more frequently in private practice. Pregnancy is perhaps one of the most serious complications, and 3 cases occurred in the hospital during the period reported, though only one is included in the number having radical operation with recovery. The fetus was about the third month. In this case the fibroid was so low down in the neck of the uterus that it blocked the birth canal. One other came in for radical operation, the tumor being rather large, springing from the uterus in front, about on a level with the internal os, and was locked under the symphysis pubis. She was in the fifth month, had some fever and was decidedly sick. Under ether the tumor was disengaged without operation. The cervical canal was comparatively free and she was allowed to go to time. She was delivered of a living child without accident. The third patient had a small fibroid near the fundus and required no treatment.

I have seen a number of cases in private practice in which women with large fibroids have been safely delivered. As a rule I believe that fibroid tumors grow very much less, and in one case a very large fibroid has entirely disappeared 12 years after I delivered the patient of a living child. I have already made a report to this society on the complication of fibroids, and I will not take time for its discussion now.⁶

The most serious complication that occurred during all this time is not reported in these cases because the woman was not operated upon for fibroid but was operated upon for appendicitis. The fibroid was not touched.

The woman, aged 34, was nulliparous, and the fibroid which was very symmetric, round and hard, extended as far as the umbilicus. She had no symptoms from this growth and was in perfect health and refused to have anything done for it. She had an ordinary attack of catarrhal appendicitis which ran along until the appendix became infected; an abscess formed and she was very septic when admitted to the hospital. Fecal matter was passing out from the bladder as well as from the rectum. The mass was as large as an orange. I did not touch the fibroid but opened down upon the appendix, washed out the pus cavity and found that the opening of the intestine into the bladder was beyond my reach unless I removed the fibroid. I tamponed the opening with gauze and left her with an open wound. She was pretty sick for several weeks but recovered without any fistulous opening and had perfect control of the bladder with quite a decided diminution in the size of the fibroid. She has now been in very good health for some 3 years. In a case like this, operation ought to be done early in the history of the appendicitis and the tumor dealt with afterward.

Another complication of fibroid for which I operated several years ago, was one with extensive adhesions so that the tumor could not be raised out of its bed, and no cleft could be found between the layers of the peritoneum and the capsule of the tumor, even when I had cut down half an inch from this almost

fibrous mass of adhesions. I only saw this one case, and after working half an hour with no success I closed the wound up and the woman recovered not only from the operation, but her fibroid rapidly diminished in size, and she returned after a few years to good health.

It is certain that fibroid tumors have a definite period of growth, but the law which governs this growth is not yet clearly understood. There seems to be in a large number of such tumors a long period of what may be called maturity or a stationary state, in which there are no symptoms given by the patient that refer to the fibroid, and in some cases (but not a large number) the fibroid disappears, leaving the woman well. It is not possible to tell in advance what will happen to a medium-sized tumor when it is first found. My rule now is to remove by operation any fibroid that is threatening life by hemorrhage, any soft myoma that is rapidly growing, any very large tumor that causes pressure upon the adjacent organs so as to make an invalid of the woman, or any tumor that seems to be undergoing a degenerative change, as is evidenced by general sickness, and especially by rise of temperature and soreness across the abdomen.

On the other hand, small fibroids have remained almost stationary under my personal observation for 15 years and are still in pretty much the same condition as I first found them. A few tumors have disappeared without my knowing the adequate cause. It is my firm conviction that no treatment other than surgical is of much service; but if a patient declines for any reason, such as heart lesion or kidney disease, to have surgery done, then galvanism will do more than any other remedy in intramural growths. In those that are most likely to require emergency treatment in hemorrhage, etc., galvanism, if intelligently and persistently used, relieves a large number of women of their symptoms, and cures a few patients.

ELECTRICITY IN MEDICINE.¹

BY

JAMES J. WALSH, M.D., PH.D.,

of New York City.

Every new discovery in electricity has been enthusiastically welcomed by certain medical men as sure to be of great service in the treatment of diseases. Over one hundred years ago, when Galvani observed the twitching of a frog's legs, he considered that the phenomenon was due to the presence of animal electricity in the tissues, and great hopes were at once raised that at last an important therapeutic secret had been discovered, and that some method for treating the disease would surely result. Notwithstanding the repeated failures since then, each new advance in electricity is still welcomed as sure to give great medical results. The makers of toys say that there is no need to make new toys each year, as there are new babies for whom the old toys are quite a novelty. Successive generations of medical men have found new toys in electric appliances and will doubtless continue to do so.

It is needless to review the rise and fall of waves of interest in electric therapeutics. Some of the recent phases of the subject, however, are of especial interest. A decade or so ago d'Arsonval, a distinguished French electrician, showed that it was possible to subject human beings to electric currents of very high frequency and

¹Read before the Celtic Medical Society, of New York City, November 25, 1903.

so place them in the midst of a highly charged electric field. I remember seeing in Paris the apparatus for this purpose, a series of wire coils forming a sort of cage, within which the patient sat. During the course of the treatment the individual within the coils became so highly charged with electricity that an incandescent light held between his hands, though unconnected with the source of electric energy by any system of wire or other metallic circuit, glowed just as if it were in circuit. For a time at the Salpêtrière great results were expected from treatment by this electric method. It is now almost entirely abandoned, and is only in use by those who find wonderful curative effects in all forms of electricity.

When the röntgen rays were discovered the assurance came that great therapeutic possibilities were about to be accomplished. Exaggerated and premature accounts of benefit derived in deep-seated malignant disease and in Hodgkin's disease seemed to justify the great expectations. We are now once more in the period of reaction and realize most of the limitations of the application of the röntgen ray, though not very clearly, and with many alluring, inexplicable results to tempt us to continue their use even in apparently hopeless cases.

From another standpoint some very interesting sidelights on electricity have been thrown. The new physical chemistry seems to show that atoms do not act in chemistry merely as masses of matter, but as masses of matter bearing a certain charge of electricity. These are the so-called ions of the modern ionic theory of the constitution of matter, and here once again there seems to be ground for hope of electric applications in medicine. About a year ago, however, I heard Professor Loeb, then of the University of Chicago, now of the University of California, in a series of lectures at Columbia in which he discussed the application of the ionic theory to physiology and biology, declare that nature had so safeguarded the electric conditions, and especially the equilibrium of electric forces within the body, that any disturbance of this by external electric force was utterly impossible. We are so constantly placed in varying electric conditions because of alterations in the electricity in the earth and the air, that if this were not the case, animal life would be in almost constant danger from the magnetic storms that are so frequent.

Professor Loeb also declared that whatever effect the röntgen rays had was not due to the fact that they were electric phenomena, but that they were related more closely to light than to electricity. Finsen's experiments and demonstrations on light, Loeb considered of very great interest, as furnishing the reason for the effects produced by the röntgen ray in animal tissues.

Physiologic investigations, as well as recent progress in physical chemistry, seem to confirm entirely Galvani's original idea of the existence of animal electricity apart from any external electric energy. This is a curious confirmation, nearly 125 years after Galvani's original announcement of his ideas, which, for at least a century of the intervening period, were considered, in this at least, to be without foundation. If such animal electricity exists it is easy to understand how thoroughly protected from external electric influences it must be for life to persist in spite of the varying magnetic field of earth and air. Even when men or animals are killed by electricity it is not by a disturbance of the electric equilibrium within them, though disturbances of the electric equilibrium may occur rather easily and indeed represent an important element at least of the mode of action of vital force in the tissues. Death from electricity is usually considered to take place from shock and consequent absolute inhibition of the large nerve cells of the central nervous system.

All of this, then, would seem to add to the improbability that external electric energy can ever be employed

successfully for the modification of diseases and vital processes in such a way as to bring about a natural cure, for animal electricity is necessarily thoroughly isolated from all outside influences, and we cannot hope to bring about any important modification of it.

It would seem, then, that no wondrous effects are to be hoped for from electricity in medicine, yet this does not proclaim it as absolutely useless. There is undoubtedly an important suggestive element in treatment by any form of electricity. This will produce a mental influence that reacts upon the physical condition of the patient. Hence the employment of different forms of electricity may do great good, especially in functional nervous diseases. It must not be forgotten that the eddyites claim to have many thousands of cures to their credit. Their statistics would compare very favorably with those of the electric therapists. To my mind, the improvement noted in such cases may have been brought about in the same way. The physician, however, cannot use the wonderful power that the religious instinct has over people to effect cures. He can and should use the suggestive influence that electric effects of various kinds undoubtedly do produce.

It is well known that static electricity will, under many circumstances, raise blood-pressure and cause an increased flow of blood to the cutaneous surface of the body. This of itself may be extremely important. Meltzer showed recently that the circulation in nerves depends on free connection with two portions of the body, the central nervous system and its peripheral branches. An increased circulation in the skin, then, may mean great improvement in nervous nutrition. Undoubtedly many of the improvements noted in nervous diseases are due to this hitherto not well understood circulatory mechanism.

In spite of this more or less pessimistic view of the present and possible effects of electricity in medicine, there are many interesting therapeutic prospects on the electric medical horizon at the present moment. Recent thoroughly authentic reports show that some of the intractable facial neuralgias, which have hitherto constituted one of the most serious problems in neurology and surgery, yield promptly to the röntgen ray treatment. Upon the severe and almost unbearable pains which accompany certain of the internal cancers when approaching their fatal termination the röntgen rays seem to have a like wonderful effect. This alone demands their employment, though no hope of even temporary improvement of the actual physical condition of the patient may be entertained. During the present year, beside favorable reports in Hodgkin's disease, in which, unfortunately, the good results are now recognized as only temporary, there have been some very promising results obtained in splenomedullary leukemia. There was a marked reduction in the size of the spleen after three weeks' treatment, and the blood showed corresponding improvement with this favorable splenic progress.

Apparently we are getting to know more about the class of rays, whether light or electric, or on the borderland between these two modes of energy, which somehow affect cellular energy in animals very powerfully. It is possible then that the very near future, seeing the rapid progress of electric science in these matters in recent years, may bring us some form of electricity that will prove alterative, not directly of the animal electricity of the tissues, but of certain modes of cell life. We may thus possibly secure physical remedial agents of many kinds. There are at least three different kinds of rays in the radium emanations. We are only on the threshold of our knowledge of radioactivity and the development of this interesting department of science may bring us physical remedies quite as powerful as the various chemical substances that we have used empirically, yet very successfully withal, for centuries, without quite knowing their mode of action.

THE PRELIMINARY REPORT OF A SERIES OF METABOLISM OBSERVATIONS MADE IN ATROPHIC ARTHRITIS, HYPERTROPHIC ARTHRITIS, OSTEITIS DEFORMANS AND THE NORMAL.

BY

JOEL E. GOLDTHWAIT, M.D.,

AND

CHARLES F. PAINTER, M.D.,

AND

ROBERT B. OSGOOD, M.D.,

of Boston, Mass.

The following communication represents a part of the work which has been carried on by, or under the direction of, the writers during the past few years in the endeavor to gain a better understanding of the etiology, pathology, and treatment of the so-called rheumatoid diseases. That the knowledge of these diseases is very unsatisfactory no one can question who has taken time to look over the literature as it appears today, and although a paper upon this subject may seem strange coming from men who are practising orthopedic surgery, it, nevertheless, represents work which seems to be necessary, as the treatment of these various joint conditions cannot be intelligently planned until the etiology and pathology is known.

As a part of the systematic study of these diseases, Mr. F. H. McCrudden has been, during the past 3 years, conducting a series of metabolism observations in the various types of this disease.

The work has been carried on in the physiologic laboratory of the Massachusetts General Hospital, and in its development Dr. Franz Pfaff and Dr. Elliot P. Joslin have been most helpful with their suggestions.

The report of the work performed by Mr. McCrudden during this period is here presented. It is naturally preliminary in character, as many more observations must be made before any conclusions can be reached, but it is presented in this form in the hope that others may be interested to undertake similar lines of work and that the time which it was necessary to spend in the preliminary experimentation may be saved to them. It is also probable that these reports, studied in connection with similar work which may be undertaken by other observers will have additional value.

In order that the report may be properly understood it will be necessary to state briefly the clinical characteristics of the diseases designated by the terms "atrophic arthritis," "hypertrophic arthritis," and "osteitis deformans." There has been much confusion in the use of terms, and it will be necessary, until the whole subject is placed upon a definitely scientific basis, for each writer to explain the terms used by him to indicate the various types of the disease.

Atrophic or rheumatoid arthritis is used to designate a type of disease seen in both men and women at any period of adult life; progressive in character and showing in the active stage an increase of the normal joint fluids as well as swelling and infiltration of the periarticular structures. In the fingers the first or proximal row of phalangeal articulations is chiefly involved, the swelling giving the spindle-shaped appearance. In the other joints the swelling presents different appearances, depending upon the anatomic conditions, but in all as soon as the process begins, atrophic changes in the cartilage and other joint structures appear. This is clearly shown in the röntgen ray, and becomes more noticeable as the disease progresses. The joints, as the result of the gradual absorption of the swelling, become smaller and ultimately are smaller than normal, owing to the atrophy in contrast to the permanent increase in size, as is seen in hypertrophic arthritis.

Any of the joints may be affected, and without treatment there is usually a gradual progression of the dis-

ease until all are involved, although as a rule only a few joints are actively affected at one time. The disease naturally produces contractures and deformity, and is one of the most crippling of the various rheumatoid diseases.

Hypertrophic or osteoarthritis is the term used to designate a type of disease seen in both men and women at any time during adult life, but most commonly at or past middle life, in which there is thickening of the edges of the articular cartilages with ultimate ossification, a true hypertrophy instead of the atrophy as seen in the rheumatoid type. There is, aside from this thickening, little, if any periarticular swelling and no increase of the joint fluids, unless from the mechanical irritation which the nodes or hypertrophied edges of the cartilage may represent. Any joint may be involved, and while usually only one or two joints are affected, occasionally the process is quite general. In the fingers the distal row of articulations is the one chiefly affected, and the nodes as they appear are in marked contrast to the soft spindle swellings of the atrophic type. In hypertrophic arthritis the hypertrophy is apparent very early in the process, the same as the atrophy in atrophic arthritis, when examination is made with the röntgen ray.

Osteitis deformans, or Paget's disease, needs less description, as there is usually less confusion in the use of this term. The disease is characterized by marked thickening with bowing of the shafts of the long bones, and with thickening of the flat or squamous bones. It is slowly progressive in character, and results in considerable deformity, but with comparatively little involvement of the joints, the joint symptoms being due to strain resulting from the bowed or distorted bones.

In connection with this work, in order not to duplicate that which has previously been done, it has been necessary to review carefully all the literature bearing upon the general subject of metabolism.

This has involved much labor, and as many of the papers are without value unless studied in connection with others, they have been carefully abstracted, and will be published shortly in the hope that in this form they may be of assistance to others who are doing similar work. After such a study the need of further work must be apparent at once, if any real progress is to be made in the treatment of these crippling diseases.

The report of the chemic work, the description of the technic, and a brief outline review of the literature covered by this investigation follows.

* * * * *

Before performing any experiments on rheumatic patients, it seemed advisable to make a thorough study of the literature concerning the metabolism in gout. Since the subject of gout and that of uric acid are so intimately connected in the literature, an especially exhaustive treatment of the bibliography of the chemistry of uric acid and of the status of uric acid in the physiology and pathology of mammals and birds was taken.

The present time seems an appropriate one to undertake such a work. For some years it has been known in a general way that the nucleoproteids have great influence on the excretion of uric acid. The recent experiments of Burian and Schur¹ have defined this influence and have given us a quantitative expression of its importance. These authors, too, have given the proof that it is the purin bases of the nucleoproteids, and, in fact, the purin bases alone, free or combined in nucleoprotein that have any influence on the excretion of uric acid so far as the food is concerned.

The last article by Emil Fischer² on the subject of the purin bodies shows us that uric acid and the purin bases are all simple derivatives of purin and that uric acid is the highest oxidation product of the purin group. It is clear then why the purin bodies are of such importance as a source of uric acid.

W. His³ has recently applied the methods of the

science of physical chemistry to the determination of the behavior of uric acid in solutions. As a result of his work, some views concerning the solubility of uric acid in pure water, in various solutions, and in urine, and the effect of various agents on the solubility, which have been generally held for many years, have been overthrown.

Physical chemistry has shown us that the acidity and alkalinity of many solutions of complex mixtures of electrolytes such as blood and urine can not be determined by titration methods. Only recently has an accurate electrochemic method been offered by which we could determine the acidity of urine and the alkalinity of blood.

By means of this method Höber⁴ has found that the prevailing views concerning the acidity of the urine and the alkalinity of the blood are far from correct. The work of His and Höber taken together puts an end to many theories concerning the uric acid in the blood and urine, and to any scientific basis for the alkali therapeutics in gout.

We have undertaken to make a thorough study of the pure chemistry of uric acid and its decomposition products, and of those purin bodies which have any physiologic importance; of the behavior of uric acid in solutions of pure water, in solutions of simple and mixed electrolytes, and of organic compounds and in urine and blood.

We have attempted to study all the research that has been done on the physiology of uric acid—the effects of food, and of qualitative and quantitative changes in the food, the effects of alcohol, exercise and other physiologic functions—and also the research on the uric acid in pathologic conditions of all kinds, especially in gout and the rheumatic diseases. We hope also to make a study of the literature of the physiologic and pathologic metabolism of the inorganic salts.

When this work is done we shall be in a position to undertake research in the most profitable directions. The amount of literature covered so far has indicated many lines of valuable work.

Another point of importance only recently established by the work of Burian and Schur,⁵ Soetbeer and Ibrahim⁶ and Salkowski⁷ is the fact that uric acid is excreted in great part unchanged by mammals. This is certainly a final death blow to the old view that uric acid is an antecedent of urea in the destructive metabolism of proteid.

The method of carrying on the metabolism experiments will be described first with the details of the methods of analysis of the food, urine, and feces.

Technic.—The general method of performing the experiments, finally developed, was that of McCrudden.⁸ The details of the technic used in the earlier experiments were not quite the same as in the later ones, but they did not differ in any principle that would tend to vitiate the earlier results.

The experiments were generally carried on through 8 days. Each patient was weighed before and after the experiment.

Food.—The patient was in each case allowed to have what he wanted to eat and drink both in regard to quality and quantity. The food he ate was weighed and the same weight of each food was taken for analysis. Only food which was practically homogeneous throughout was given so that the sample taken for analysis would presumably have the same percentage composition as the portion eaten by the patient. The food taken for analysis was well mixed, and, after addition of a little HCl to retain any nitrogen which might tend to escape as ammonia, the mass was evaporated to dryness. It was then well mixed with alcohol and evaporated to dryness again and the mixing with alcohol and evaporation was repeated once. This last device brings the food into a very dry condition so that it can be finely powdered in a grinder. The fat was sometimes extracted with naphtha if it interfered with the process of grinding.

The naphtha does not extract any calcium, magnesium, sulfur, or nitrogen. "A" and "B" are the results obtained by the analysis of 2 equal fractions of the same food mass which had been extracted with naphtha. "C" is the result of the analysis of an equal fraction of food to which a corresponding fraction of the naphtha solution had been added.

After the food was crushed so that it would pass through a fine-meshed sieve samples for analysis were obtained by quartering. The food was thoroughly mixed with a large spatula and then made into a little circular pile a couple of inches high.

The pile was divided into 4 nearly equal quarters. Two opposite quarters were rejected, and the other 2 well mixed, made into another little pile, and quartered again. The mixing and

	CaO.	MgO.	S.	N [expressed by $\frac{N}{16}$ H ₂ SO ₄ used (Kjeldahl.)]
"A".....	.1370	.0852	.1451	39.62 cc.
"B".....	.1356	.0858	.1480	39.76 cc.
"C".....	.1354	.0848	.1452	39.68 cc.

quartering were repeated until there was about enough food left for 1 set of analyses. Samples for duplicate and triplicate analysis were obtained in the same way.

The following results show that the mixing can be very complete. The samples "D," "E," and "F," represent as nearly as possible entirely different portions of the food.

	CaO.	MgO.	P ₂ O ₅ .	N [expressed by $\frac{N}{16}$ H ₂ SO ₄ used (Kjeldahl.)]
"D".....	.1026	.1128	.1672	20.41 cc.
"E".....	.1012	.1112	.1680	20.64 cc.
"F".....	.1016	.1120	.1659	20.46 cc.

Urine.—The urine was analyzed daily, instead of in bulk for the week, in order to see if there were a daily variation in the amounts of any of the constituents. It was collected from eight each morning until eight the following morning. If it were collected from evening to evening considerable of the elements in it might have come from the previous day's food. The patient emptied his bladder just before eight each morning, for complete separation of the different days' urines, and just before stools, in order to separate the stools and the urine.

Feces.—The stools were saved and analyzed. The patient was starved from noon of the day before the experiment until the following morning, in order that the feces which came from the food given before the experiment could be separated as much as possible from that given during the experiment. Half an hour before breakfast on the first day of the experiment, a mixture, consisting of 10 gm. charcoal, 10 gm. acacia, and 60 cc. peppermint water, well shaken, was given the patient. This blackens the first stool belonging to the experiment. The patient was starved from noon of the last day of the experiment until the following morning, and a charcoal mixture was given him half an hour before breakfast on the day after the experiment. The feces was saved until it began to come black. The stools were all mixed together and, after addition of a little HCl to retain nitrogen, the mass was evaporated to dryness, powdered, well mixed together, and placed in a weighing bottle, preparatory to taking samples for analysis. Weighed amounts of filter-paper, nearly free from ash, were used after stools, and the same weight of the paper was mixed with the food used for analysis to offset the small amount of ash introduced into the feces in the paper.

Methods of Analysis.—The urine was first made up to a definite volume, 1,000 cc., 1,500 cc., or 2,000 cc., according to the amount voided. All analyses were made in duplicate.

Potassium and Sodium.—The method of Salkowski⁹ and Munk¹⁰ was used for the determination of the alkalies. To 100 cc. of urine, ammonia and about 25 cc. barium hydroxid solution were added. The solution was shaken and CO₂ was passed through it to precipitate all the barium. It was then made up to 200 cc. with distilled water and passed through a dry folded filter. One hundred cc. of the filtrate was made acid with HCl and evaporated to dryness in a platinum dish. After the residue was thoroughly dry, it was placed in a muffle furnace and incinerated at a low red heat. The charred mass was treated with water, to dissolve the sodium and potassium salts. A little (NH₄)₂CO₃ and ammonia were added to precipitate any remaining trace of barium, and then the solution was filtered. The filtrate was made acid with HCl and evaporated to dryness. The ammonium salts were volatilized at a low red heat, and the residue of potassium and sodium chlorids weighed.

To determine the amount of each of these alkalies present two different methods were used—the gravimetric method, and the volumetric method.

In the gravimetric method the chlorids were dissolved in a little water, and some PtCl₄ was added to the solution. This solution was evaporated at a low temperature to a syrupy consistency. Fifteen cc. of alcohol was then added and the solution was allowed to stand about 15 minutes. The potassium is precipitated as K₂PtCl₆. The precipitate was filtered off and washed by decantation through a filter, care being taken to get as little of the precipitate as possible on the filter paper. The K₂PtCl₆ on the filter was washed back into the dish. The liquid was evaporated and the potassium salt dried to constant weight in a hot closet. From the weight of the K₂PtCl₆ the weight of the corresponding amount of KCl can be calculated. The weight of the combined sodium and potassium minus the weight of the potassium chlorid gives the weight of sodium chlorid. The corresponding amounts of the oxids are calculated from the chlorids.

In the volumetric method the amount of chlorin in the mixed chlorids was determined by titration with a solution of AgNO_3 containing a known percentage of Ag. From the weight of the combined chlorids and the weight of the chlorin, we can calculate the amounts of potassium and sodium present.

Calcium.—An aliquot part (50 cc., 100 cc., or 200 cc.) urine was made slightly ammoniacal until a precipitate of phosphates came down. HCl was then added drop by drop until the precipitate just disappeared. After that ammonium oxalate was added to precipitate the calcium as oxalate and considerable sodium acetate to lessen the dissociation of the HCl and make the precipitation complete. The solution was then allowed to stand over night on the water-bath. In the morning the calcium oxalate was filtered off, washed with hot dilute ammonium oxalate solution, dried, ignited to constant weight in the blast lamp, and weighed as calcium oxid.

Neubauer and Vogel in their textbook of urine analysis give this method, but state that the results are a trifle lower than the results obtained by the long Frezenius methods. Richards, McCaffrey, and Bisbee¹¹ have recently shown that the older methods are inaccurate. These authors have given us a very accurate method for the determination of calcium in the presence of magnesium. We compared the results obtained in the method used by us with the results obtained by the Richards, McCaffrey, and Bisbee method.

A solution was made up containing both MgCl_2 and CaCl_2 . Five portions of 50 cc. each were measured out. To the first 3 portions, sodium phosphate was added and the calcium determined by precipitation in a dilute HCl solution containing sodium acetate. Numbers 4 and 5 were analyzed by the method of Richards, McCaffrey, and Bisbee.

1.	2.	3.	4.	5.
.0935	.0940	.0942	.0939	.0938
		.0939	.0939	

The results seem to indicate that the method is as accurate as that of Richards, McCaffrey, and Bisbee, and therefore more accurate than the Frezenius method.

Analysis of the precipitate of calcium oxalate after incineration shows that it sometimes contains a very little P_2O_5 . This is what probably makes up for the very slight solubility of the calcium oxalate in the dilute acetic acid solution. The table shows how much P_2O_5 was found in weighed quantities of CaO .

CaO .	P_2O_5 .	CaO .	P_2O_5 .	CaO .	P_2O_5 .
.0654 gm.	.0006 gm.	.0604 gm.	.0005 gm.	.0716 gm.	.0002 gm.
.0680 "	.0008 "	.0610 "	.0006 "	.0724 "	.0005 "
.0505 "	.0009 "	.0650 "	.0007 "	.0542 "	.0004 "
.0502 "	.0006 "	.0650 "	.0008 "	.0564 "	.0004 "
		.0652 "	.0008 "		

Magnesium.—The determination of magnesium was carried out by a method given in Neubauer and Vogel's book on urine analysis. The filtrate from the calcium oxalate (see determination of calcium) was evaporated to rather small bulk. Enough ammonia was added until the solution contained one-third its bulk of ammonia of specific gravity .096. Sodium ammonium phosphate slightly in excess of the amount required to precipitate the magnesium was added drop by drop with constant stirring of the solution. The solution and precipitate were then allowed to stand in contact over night. The next day the precipitate of magnesium ammonium phosphate was filtered off, washed with a solution consisting of 1 part alcohol, 1 part ammonia and 3 parts water, dried, ignited, and weighed as $\text{Mg}_2\text{P}_2\text{O}_7$. From this the amount of MgO was calculated.

Total Phosphorus.—This consists of the phosphorus as phosphate and the phosphorus in organic combination.

Three different methods have been used to oxidize the organic matter in order to get the organic phosphorus in the form of phosphate, so as to precipitate it with ammonium molybdate.

In the fusion method, the standard method by which to test the accuracy of other methods, 50 cc. of the urine was mixed with 3 gm. of KNO_3 and 1 gm. Na_2CO_3 and evaporated to dryness. The residue was fused until it was colorless and dissolved in water. After slightly acidifying with HNO_3 , ammonium molybdate, prepared according to Blair,¹² and ammonium nitrate were added.

The solution was allowed to stand at a temperature of 45°C . for about 24 hours. It was then filtered and washed free of calcium and magnesium by decantation through a small ashless filter with an acid solution of ammonium nitrate. This solution is made by mixing together 100 cc. of ammonia (sp. gr. 0.96), 325 cc. of nitric acid (sp. gr. 1.2), and 100 cc. water. This precipitate of ammonium phosphomolybdate was then dissolved in ammonia. After neutralization with acid, ammonia was added until the solution contained one-third of its volume dilute ammonia (sp. gr. .096). Magnesium mixture, pre-

pared according to Blair, was added drop by drop with constant stirring and the solution was allowed to stand over night. The next day the magnesium ammonium phosphate was filtered off and washed with a dilute solution of alcoholic ammonia, consisting of 1 part ammonia, 1 part alcohol, and 3 parts water, until free from chlorids. The precipitate was then dried, ignited to constant weight, and weighed as $\text{Mg}_2\text{P}_2\text{O}_7$. From the weight of $\text{Mg}_2\text{P}_2\text{O}_7$ the amount of P_2O_5 can be calculated.

Ammonium molybdate, according to Blair, is prepared as follows: 100 gm. of pure molybdic anhydride is thoroughly mixed with 400 cc. of cold distilled water, 80 cc. of strong ammonia (.90 specific gravity) is added and when the acid is all dissolved the solution is filtered. The filtrate is poured slowly, with constant stirring, into a solution of 400 cc. strong nitric acid (specific gravity 1.42) and 600 cc. distilled water. After allowing it to settle for 24 hours the solution is filtered. It is then ready for use.

Magnesia mixture, according to Blair, is prepared as follows: 110 gm. of crystallized magnesium chlorid ($\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$) is dissolved in water and the solution filtered. A second solution is prepared by dissolving 28 gm. of ammonium chlorid in water. A little Br. water is added and the solution is boiled, to oxidize any iron present, and to the hot solution a little ammonia is added, to precipitate the iron. This solution is filtered and the filtrate mixed with the solution of MgCl_2 . Enough ammonia is added to make the solution smell decidedly ammoniacal and the whole is diluted to about 2 liters, well shaken and allowed to stand several days. It is then filtered again and is ready for use.

A second method which was used to oxidize the organic matter was to boil the urine with nitric acid and potassium permanganate. The KMnO_4 was added a little at a time until a brown precipitate of MnO_2 showed that all organic matter had been oxidized. A little sulfurous acid was used to dissolve the MnO_2 and then the SO_2 was boiled off. Ammonium molybdate and ammonium nitrate were then added to the solution and the analysis continued in the same manner as before.

A third way was to oxidize the organic matter with potassium chlorate and hydrochloric acid. Hydrochloric acid was added to the urine, the solution was heated to boiling and potassium chlorate crystals were added a little at a time to the boiling solution until it became colorless. Ammonia was then added until the solution was nearly neutral. Ammonium nitrate and ammonium molybdate were added and the analysis carried on from this point in the same way as in the other methods.

That the permanganate method gives the same results as the fusion method can be seen from the following table:

	1	2	3	4	5	6	7	8
Permanganate0886	.0788	.0684	.0546	.0537	.0561	.0570	.0538
Fusion0886	.0778	.0693	.0548	.0544	.0568	.0582	.0542

The following tables show that the chlorate method gives the same results as the permanganate method:

	9	10	11	12	13	14	15
Permanganate0742	.1444	.0836	.1410	.1414	.1540	.1486
Chlorate0750	.1456	.0850	.1420	.1397	.1558	.1452

	16	17	18	19	20	21	22
Permanganate1658	.0704	.0790	.0798	.0898	.0762	.0644
Chlorate1674	.0690	.0808	.0806	.0908	.0756	.0654

The figures represent the P_2O_5 in 50 cc. of 22 different urines. One determination was carried out by each method. The time at our disposal did not permit us to carry out double analyses by each method. The results, however, show that for our purposes the methods are accurate.

Phosphates.—To 50 cc. of urine, ammonia was added until the solution contained about a third its bulk of dilute ammonia (specific gravity, .096). A few cubic centimeters of magnesia mixture were then added and the solution was allowed to stand over night in order that the phosphates might precipitate completely. The next day the precipitate was filtered and washed with dilute alcoholic ammonia until free from chlorids, and then dissolved in dilute nitric acid. The phosphate in this solution was determined in the usual manner by precipitation with ammonium molybdate, solution of the precipitate in ammonia and reprecipitation of the phosphate with magnesia mixture.

Total Sulfur.—Two methods were used in the determination of the total sulfur in urine. One method is that of Mohr;¹³ 50 cc. of urine was evaporated to dryness and then heated for

some time with concentrated HNO_3 . The nitric acid was then evaporated and the solution treated with hydrochloric acid and evaporated to dryness several times to get rid of the nitric acid. The residue was taken up in a little dilute hydrochloric acid and filtered. The filtrate was heated to boiling and BaCl_2 was added drop by drop. The boiling was kept up for about an hour and then the precipitate was allowed to settle in a warm place for a few hours. It was then filtered off, dried, ignited and heated to a constant weight. From the weight of BaSO_4 the amount of S can be calculated.

In the other method the sulfur is oxidized by hydrochloric acid and potassium chlorate exactly as in the oxidation of the phosphorus in the chlorate method.

Both methods give about the same results.

	1	2	3	4	5	6	7
HNO_3 method.....	.0401	.0282	.0369	.0502	.0476	.0466	.0450
Chlorate method.....	.0397	.0226	.0356	.0504	.0485	.0478	.0442

The figures show the sulfur in a measured amount of 7 different urines. One determination was made by each method.

Nitrogen.—The determination of nitrogen in urine was carried out by the following modification of the Kjeldahl method:

Five cubic centimeters of urine was boiled with 15 cc. H_2SO_4 , 5 gm. K_2SO_4 , and 5 cc. CuSO_4 until colorless. The solution was made alkaline with sodium hydroxid and the ammonium distilled over into 50 cc. of tenth normal H_2SO_4 solution. The excess of H_2SO_4 was titrated with tenth normal NaOH .

ANALYSIS OF FOOD AND FECES.

Analyses were made in duplicate and sometimes in triplicate.

Calcium and Magnesium.—An aliquot part of the food or feces usually about 15 gm. to 20 gm. food or about 1 gm. feces, was incinerated in a platinum dish. The ash was treated with concentrated HCl and evaporated to dryness a couple of times. The residue was heated for 2 hours in the hot closet at 110°C . to make the silica insoluble, then extracted with a little dilute HCl , filtered and washed. In the earlier experiments the calcium and magnesium were determined in the filtrate by the long Frezenius method of double precipitation of calcium after getting rid of iron and phosphoric acid. The method used for the determination of calcium and magnesium in urine was found, however, to give results which agree with the Frezenius method, and with the newer Richards, McCaffrey, and Bisbee method, so that it was used in the later experiments.

Phosphorus.¹⁴—An aliquot part of the food or feces, about 5 gm. to 10 gm. food or 0.5 gm. to 1.0 gm. feces, was allowed to stand in the cold for about 24 hours with 30 cc. to 40 cc. of concentrated sulfuric acid. The mixture was then heated and NH_4NO_3 was added in small portions until the solution became light yellow in color. It was then cooled, diluted slightly, and made almost neutral with ammonia. The phosphate was precipitated by addition of ammonium nitrate and ammonium molybdate, and the analysis proceeded with from this point as in the determination of P_2O_5 in urine.

Nitrogen.—An aliquot part of the food or feces, about .7 gm. to 1.0 gm. food, or about .5 gm. feces, was heated with 20 cc. concentrated H_2SO_4 , 5 cc. CuSO_4 , and 10 gm. K_2SO_4 until solution was colorless. The solution was then made alkaline with sodium hydroxid, the ammonia distilled into 50 cc. tenth normal sulfuric acid solution, and the excess of acid determined by titration with normal sodium hydroxid.

Sulfur.—An aliquot part of the food or feces, about 1 gm. to 1.5 gm. feces, or about 1.5 gm. to 3.0 gm. food, was oxidized by fusion with 15 gm. NaOH and 3 gm. KNO_3 . The mass was dissolved in HCl and evaporated to dryness several times with concentrated HCl to get rid of the nitrate. The residue was heated 2 hours in the hot closet at 110°C . to make the silica insoluble, and then extracted with dilute HCl and filtered. The filtrate was heated to boiling and the sulfate precipitated by addition of BaCl_2 solution drop by drop. The BaSO_4 was allowed to settle in a warm place for about 4 hours, then filtered, washed free from chlorides, dried, and ignited to constant weight. The NaOH and KNO_3 used in the fusion were supposed to be pure, but blank analyses of the reagents were always made, since there was always obtained a slight blank test for sulfur due in part, perhaps, to the S in the gas.

Results.—Before beginning metabolism experiments the urines of a number of patients with arthritic diseases were examined quantitatively for Ca , Mg , P_2O_5 , K , and Na . The following table shows the results of the analysis of several urines. The quantities are those found in the urine for 24 hours.

The normal amounts of these inorganic constituents in the urine are very variable. The total P_2O_5 varies from 1.5 gm. to 5 gm. per day, and averages 3.5 gm. according to Neubauer and Vogel.¹⁵ The CaO varies

from .12 gm. to .25 gm., the MgO from .18 gm. to .28 gm., Na_2O from 4.2 gm. to 7.4 gm., and K_2O from 2.3 gm. to 3.9 gm., on an ordinary mixed diet.

Name.	K_2O .	Na_2O .	MgO .	CaO .	Total P. as P_2O_5 .	Phosphates as P_2O_5 .
M. P.....	3.71 gm.	7.70 gm.	.10 gm.	.26 gm.	1.13 gm.	1.05 gm.
Mrs. J. P.....	2.07 "	4.67 "	.09 "	.19 "	.93 "	.87 "
Mrs. S.....	1.02 "	1.98 "	.12 "	.38 "	1.41 "	1.17 "
B.....	4.50 "	4.29 "	.13 "	.32 "	1.47 "	1.47 "
Mrs. E.....	4.81 "	.05 "	.28 "	.95 "	.92 "	
Mrs. B.....	2.63 "	4.42 "	.13 "	.05 "	1.36 "	1.34 "
Mr. S.....	9.41 "	.16 "	.24 "	1.94 "	1.71 "	
Mr. I.....	4.84 "	2.28 "	.10 "	.26 "	1.72 "	1.70 "
A normal urine.....	3.80 "	4.07 "	.19 "	.18 "	1.87 "	1.86 "
Mr. R.....	7.82 "	1.95 "	.27 "	.15 "	1.93 "	1.93 "
McM.....	8.20 "	2.44 "	.15 "	.12 "	2.15 "	2.15 "
A normal urine.....	7.82 "	8.93 "	.26 "	.51 "	2.56 "	2.55 "

It will be noticed that in our cases the quantity of potassium in the urine is nearly always greater than the quantity of sodium. The magnesium is low, and the phosphorus low.

REPORT OF THE METABOLISM EXPERIMENTS.

First experiment on Mary P., April 27 to May 4, 1901. A case of atrophic arthritis in the active stage. Weight of patient at beginning of the experiment, 125 pounds. Weight of patient at end of the experiment, 123 pounds.

FOOD.—FIRST DAY. Water 320 cc.

Breakfast.	Dinner.	Supper.
Corn bread..... 58.5 gm.	Roast beef 78.0 gm	Bread..... 76.0 gm.
Butter..... 7.0 "	Potatoes..... 99.0 "	Butter..... 19.0 "
Milk..... 200 cc.	Bread..... 37.0 "	Milk..... 200 cc.
Charcoal mixture of 10.0 gm. charcoal, 10.0 gm. acacia, 60 cc. pepper-mint water.	Rice..... 89.0 "	
	Butter..... 18.0 "	
	Milk..... 200 cc.	

SECOND DAY. Water 120 cc.

Breakfast.	Dinner.	Supper.
Bread 55.0 gm.	Roast beef 49.0 gm.	Bread..... 53.0 gm.
Butter..... 15.0 "	Stewed corn..... 109.0 "	Butter..... 15.0 "
Milk 200 cc.	Baked potatoes. 97.0 "	Cookies..... 41.0 "
	Bread..... 44.0 "	Milk..... 200 cc.
	Butter..... 15.0 "	
	Milk..... 200 cc.	

THIRD DAY. Water 600 cc.

Breakfast.	Dinner.	Supper.
Bread..... 25.0 gm.	Milk 200 cc.	Bread..... 50.0 gm.
Butter..... 10.0 "		Butter..... 15.0 "
Oatmeal..... 127.0 "		Milk..... 200 cc.
Milk..... 260 cc.		

FOURTH DAY. Water 800 cc.

Breakfast.	Dinner.	Supper.
Bread..... 49.0 gm.	Roast beef..... 78.0 gm.	Bread..... 50.0 gm.
Butter..... 16.0 "	Potatoes..... 119.0 "	Butter..... 10.0 "
Oatmeal..... 159.0 "	Boiled onions..... 129.0 "	Milk..... 200 cc.

SEVENTH DAY.

Breakfast.	Dinner.	Supper.
Oatmeal..... 225.0 gm.	Codfish.....105.0 gm.	Bread..... 66.0 gm.
Bread..... 48.0 "	Potatoes..... 67.0 "	Butter..... 14.0 "
Butter..... 15.0 "	Bread..... 36.0 "	Milk.....200 cc.
Milk.....200 cc.	Butter..... 20.0 "	
	Milk.....200 cc.	

EIGHTH DAY.

Breakfast.	Dinner.	Supper.
Corn bread.....101.0 gm.		
Milk.....200 cc.		
Butter..... 15.0 gm.		
Salt for the week 5 "		
Sugar " " 49 "		

RESULTS.

Urine.	P ₂ O ₅ .	CaO.	MgO.
First day.....	.995 gm.	.194 gm.	.074 gm.
Second day.....	.894 "	.217 "	.078 "
Third day.....	.835 "	.078 "	.052 "
Fourth day.....	1.098 "	.219 "	.070 "
Fifth day.....	.772 "	.132 "	.042 "
Sixth day.....	1.199 "	.273 "	.088 "
Seventh day.....	.841 "	.108 "	.048 "
Total.....	6.63 gm.	1.22 gm.	0.45 gm.
Feces.....	8.07 "	6.31 "	1.46 "
Total excreted.....	14.70 gm.	7.53 gm.	1.91 gm.
Food.....	18.20 "	6.64 "	2.07 "
Retained by body.....	+3.50 gm.	-.89 gm.	+1.16 gm.

The phosphorus in the urine seems to be low, the calcium nearly normal, the magnesium low. It will be noticed that although there was a retention of some of the phosphorus and magnesium of the food by the body, yet more calcium was excreted than was taken in the food.

Mrs. E. A case of atrophic arthritis in the active stage.

FIRST DAY. Water 800 cc.

No breakfast.	Dinner.	Supper.
	Fried swordfish. 75.0 gm.	Bread..... 40.5 gm.
	Potatoes.....62.5 "	Butter..... 9.0 "
	Bread.....15.0 "	Cake..... 39.0 "
	Butter..... 2.5 "	Strawber-ries.....105.0 "
	Beans..... 46.0 "	Milk.....200 cc.
	Indian pudding.....28.0 "	Tea.....100 "

The phosphates in the urine in this case were rather higher than in the arthritic cases. They were still rather lower than the average, according to the text-books, however. The calcium in the urine was considerably higher than the average, according to the text-books. The magnesium in the urine was about normal.

The calcium excreted seems to just about balance that in the food. There was a slight retention of magnesium and a considerable loss of phosphorus.

[To be concluded.]

SARCOMA OF THE NASAL PASSAGES. AN INDUCTIVE STUDY BASED ON THE RECORDS OF 150 CASES.

BY

J. A. WATSON, M.D.,
of Minneapolis, Minn.

Professor of Laryngology, Medical Department Hamline University.

Brief reports of the histories of 4 hitherto unreported cases of this disease which have come under my own observation will form a fitting introduction to the subject matter of this article. These 4 cases are included in the 150 upon the report of which the article is based.

CASE I.—A boy of 10 consulted me on October 26, 1901. He had suffered for a month from attacks of epistaxis, becoming steadily more frequent and more severe. The bleeding was always from the left side, through which side also he was unable to breathe freely, a fact attributed by himself and his friends to the presence of clotted blood in the passages. On examination the left naris was found occluded by a rather soft, bluish-gray mass, bleeding freely on even gentle manipulation with the probe. A persevering examination, however, enabled me to conclude that it was pedunculated and attached to the outer wall of the nasal fossa, a more precise determination of its origin being impossible. With the aid of cocaine and adrenalin I removed the growth in 2 pieces by the cold wire snare. It bled freely after the first manipulation, but on severing the pedicle all hemorrhage immediately ceased. Its origin was found to be from the anterior portion of the inferior turbinate. Removal was so complete and injury to the mucous membrane so slight that it was barely possible to discover its point of origin. No cauterization or curetment was attempted. Under the microscope the growth proved to be a typical small round-celled sarcoma with large vascular spaces. There has been no recurrence in almost 2 years.

CASE II.—On March 28, 1902, a girl of 10 was brought to my office by her father. For nearly a year she had been complaining of a steadily increasing stenosis of the left nasal passage. It was now complete. There was not, and had not been at any time either pain or hemorrhage. External deformity, however, had become evident some months before. The bridge of the nose was widened, the left antral region prominent. The left nasal chamber was found to be completely filled with a reddish-gray, rather firm growth, extending to the posterior naris, apparently sessile and attached to the outer wall. The septum was free, but was pushed to the right. The growth did not bleed readily on manipulation.

Under chloroform anesthesia as much as possible of the growth was removed by snare, forceps and curet. The operation was, however, necessarily incomplete. Several successive operations were then performed under cocaine. There seemed to be no end to the growth, the quantities removed being astonishing. Finally an enormous mass was pulled away in one piece, the antrum having been apparently filled by it. The external wall of the nasal fossa was now found to be almost completely destroyed, the fossa and antrum forming one large cavity apparently entirely free from the growth. The microscopic structure was that of fibrosarcoma. There has been no recurrence in a year and a half.

CASE III.—Mrs. B., aged about 43. I saw this lady first on December 26, 1901. During the previous 2 years she had suffered and was still suffering from obstruction of the left nasal duct. She had been treated by a specialist, who passed a probe frequently, and told her that she should have an operation done in the nose, as there was a growth in the nasal passage. There was obstruction to respiration through the left side, gradually increasing until it was now complete. At times she suffered from slight pain in the face. There had never been any hemorrhage. She had recently had two attacks of facial erysipelas. There was noticeable protuberance of the left side of the face and nose, with slight exophthalmos and displacement outward of the left eye. The left nasal cavity was completely occluded by rather firm tissue, not differing much in color from that of

the normal mucous membrane. The vestibule was, however, free. It was not very easy to excite bleeding by manipulation. As much as possible of the tissue was removed during a few weeks' treatment by snare, curet, scissors and cutting forceps. Radical operation was refused. Great relief was, however, experienced, free breathing room being obtained. Microscopically the growth proved to be a typical fibrosarcoma. The patient is still under observation and the disease appears to be stationary or nearly so. The retardation of its growth may be due partly at least to the attacks of erysipelas, and it is possible that much good might be accomplished by the toxin treatment, but the patient is unwilling to have it tried at present. She has lately gone successfully through the ordeal of pregnancy and lactation, which may have had some effect on the course of the disease.

CASE IV.—A boy of 10 or 11. This case was observed by the writer several years ago in the New York Polyclinic. I have seen no report of the case elsewhere, and feel justified in recording it here. The boy complained of obstruction in the left side, and repeated epistaxis. A reddish-gray growth, half the size of a walnut, filled the cavity. It was attached by a pedicle to the quadrangular cartilage. It was removed by the cold snare, and pronounced a round-celled sarcoma by the pathologist of the institution. There was no return in several months.

Since the middle of the last century there have been reported about 200 cases of sarcoma of the nasal passages. The literature prior to that period contains many references to cases which were undoubtedly instances of this disease, but which, owing to the immature condition of the science of pathology, were reported under such titles as "bleeding polyp," "malignant polyp," "recurrent tumor," "enormous polyp causing deformity of the nose and exophthalmos," etc. The disease, then, can no longer be considered so very rare as many of our textbooks would have us believe. Gibbs, in 1902, collected the reports of 111 cases, 49 of which had been collected by Bosworth, in 1889. The present series of 150 cases, collected or reported by myself, includes all of Gibbs' cases, except a few, the reports of which were not full enough to be of any value for purposes of study or comparison. I am indebted to Gibbs' article for all the information I was able to obtain in regard to some 40 cases of the series, as I did not have access to the original reports.

Any of the different varieties of sarcoma may be found in this region. Round-celled sarcoma, and particularly small round-celled sarcoma, is of the most common occurrence. Fibrosarcoma comes next in order of frequency. Myxosarcoma occurs about half as often as fibrosarcoma. Then, in decreasing order, come spindle-celled sarcoma, melanotic sarcoma, angiosarcoma, adenosarcoma. Two cases of the series were reported as osteosarcoma, while there was 1 case of myeloid, alveolar, and lymphosarcoma. There were also 2 cases of mixed carcinoma and sarcoma, while one of the melanosarcomas was "undergoing carcinomatous degeneration." It is questionable whether the comparative frequency of melanosarcoma (about 7%) is paralleled in any part of the body except the skin and choroid. The series included a number of mixed types. In microscopic characteristics these growths differ in no respect from similar neoplasms elsewhere. In gross appearances they vary very greatly. The statement of Bosworth that they are invariably pedunculated is by no means correct. Price-Brown is probably also mistaken when he asserts that they are usually sessile, at least if he refers to the earlier stages of their growth. Many cases, sessile when they come under observation, were undoubtedly pedunculated at an earlier period, the change being brought about by pressure necrosis, ulceration, and union of opposed surfaces, almost necessary consequences of the tumor's enlargement in a practically closed cavity. I say almost necessary, but I must admit not absolutely necessary consequences, since in several instances, though the tumor filled the nasal fossa and some, at least, of the accessory sinuses, and was at all points in contact with the walls of these cavities, there was actual attachment only at its point of origin. The number of cases in which there is a distinct statement that the tumor was sessile is about equal to those in which there is a distinct

statement to the opposite effect. On the whole, it is likely that a majority of these growths are pedunculated at first.

Sarcomas of the nasal passages, like sarcomas elsewhere, are usually soft, succulent, and vascular. Not a few, however, particularly of the fibrosarcomas, are described as "rather firm," "firm," "dense," or "hard." They are very commonly of a bluish-gray or reddish-gray color, but may be pink, red, dark brown, or almost black.

The particular point of origin of nasal sarcomas is of interest from both a pathologic and a therapeutic point of view. Among those cases in which it could be determined at all—and when determined was reported—the middle turbinate and ethmoid region was the most common site, though followed closely by the septum. The growth arises comparatively infrequently from the inferior turbinate and from the floor of the nose, and still more rarely from other situations. The cases in which it commences in any of the accessory sinuses are certainly very infrequent.

The proximate cause, or causes, of sarcoma in this region is, of course, as little understood as in the case of other regions, and it is, if anything, more difficult to decide with certainty what conditions may be considered as predisposing. We look on sarcoma, as a rule, as a disease of youth and early adult life, and Bosworth maintains that this generalization holds true in the case of sarcoma of the nasal passages, that the average age of its victims is a little less than 39, and that "the very large proportion of cases" occur before 40. In 123 cases of the present series in which the age has been reported, his average of a little less than 39 holds exactly true, but a little consideration will convince us that an estimation of averages is of little value in such a case. So far from "the large proportion of cases" occurring before 40, 62 cases only occurred before that age, against 61 occurring after it. The cases were distributed as follows in the different decades of life:

	Cases.
First decade	4
Second "	18
Third "	20
Fourth "	20
Fifth "	23
Sixth "	18
Seventh "	12
Eighth "	3

The first decade appears to be comparatively exempt from, the fifth comparatively liable to the disease. Further than this, age has little or no influence. The apparent comparative immunity of the seventh and eighth decades must be due principally to the comparative rarity of life in those periods.

But the matter is different when we come to consider the question of sex. Here at least there appears to be a clear indication of predisposition in that the male sex is very much more commonly affected than the female, there having been 81 cases in males, against 46 in females. In 23 cases the sex was not reported. Whether this predisposition of the male sex to the disease is due in any degree to its greater exposure to injury and to the irritative effects of adverse atmospheric conditions is a question worthy perhaps of some consideration. In the present series however, there was a history of injury, excluding the injury of surgical operations, in three cases only, all males. In one of those cases the injury occurred 12, and in another 20 years before the onset of the disease, and can hardly be held responsible.

Let us now advert to the vexed question whether sarcoma of the nasal passages ever arises, spontaneously or as the result of operative interference, from preexistent mucous polypi, or whether such a process as malignant transformation of these neoplasms ever does occur. And first it is pertinent to inquire what degree of improbability attaches to such a transformation. I believe a very small degree. For have we not perfectly analogous

processes in the wellknown phenomena of metaplasia? Nay, further, is it not in this very type of tissue that metaplasia commonly occurs? Since we know, *e. g.*, that fibrous and myxomatous tissue may, and do under certain conditions become actually converted into bone or fat or cartilage, or other forms of connective tissue, why should it be considered incredible that they might also become converted into embryonic connective tissue, especially since the latter transformation implies nothing more than a reversion to the type from which they are admittedly derived. If it be objected that such a morphologic transformation does not imply a transformation from benignancy to malignancy, I reply, first, that the ground is not well taken, since our knowledge of the essential conditions of malignancy is so immature that the one transformation might very well involve and quite possibly does involve the other; and second, that certain morphologic characteristics are practically always accompanied by and accepted as an evidence of malignancy. But evidence of a more positive character may be discovered by an examination of the present series. Polypi are distinctly stated to have been previously present in 24 out of the 150 cases, and since a great many of the records are very incomplete, it is a fair presumption that they existed in an indefinitely larger number. This is a large proportion if it be borne in mind that the argument is, not that sarcoma frequently arises from polypi, but that polypi occasionally and rarely undergo this malignant transformation. This consideration also destroys the force of the argument that if such a transformation took place, sarcoma of the nasal passages would be very much more common than it is, owing to the prevalence of polypoid disease. While it is true that in many instances neoplasms, malignant from the commencement, might have been mistaken for polypi, it is nevertheless unlikely that such was always the case, especially as in several cases the chain of evidence seems very complete, many microscopic examinations having at first declared emphatically for the presence of benign polypi only, while later examinations demonstrated the presence of sarcomatous tissue.

As might, of course, be anticipated, nasal stenosis is the most constant symptom of this disease. Sooner or later, it occurs in practically all cases. Not only, however, does it occur more frequently than any other symptom, but it nearly always occurs earlier than any other, a fact which is of some importance, as substantiating to a certain degree the view that these growths have their origin almost invariably in the nasal fossa itself, rather than in any of the accessory sinuses. Spontaneous hemorrhages constitute the next most common symptom. Occurring alone, neither of these symptoms is any more suggestive of this disease than of many other intranasal disorders, but in combination they should invariably arouse a strong suspicion. Pain is a symptom mentioned but 24 times in the not infrequently meager records of the series. I am inclined to believe that it occurs much more frequently than this. In many instances it is distinctly stated to have been absent through the whole course of the disease. Pain, when it does occur, is very varying in type and location in different cases, sometimes severe, sharp, and neuralgic, again dull, aching, boring. Commonly it is referred directly to the growth and its immediate neighborhood, but in many cases it radiates widely and distantly. Offensive purulent, mucopurulent, or sanguinopurulent discharge greatly increases the patient's misery, and not infrequently, even in comparatively early stages, the sense of smell is impaired or destroyed. If the patient's life is sufficiently prolonged, external deformity infallibly adds to the horrors of the situation. Serious impairment of the general health is often postponed until late in the history of the disease, and a cachexia such as commonly accompanies carcinoma is rarely seen.

A consideration of the subjective symptoms, and objective appearances of the disease, as collected from the

reports of this series, makes it evident that there ought rarely be any difficulty in arriving at a positive diagnosis. It is most often confounded with angioma, fibroma, carcinoma, and mucous polypi, but all of these growths, with the possible exception of fibroma, which is in any case of great rarity, possess characteristics and manifest symptoms which ought almost invariably to make it possible to avoid such confusion. The relative dependence to be placed upon microscopic evidence, provided always that many sections have been examined from different parts of the growth, both deep and superficial, depends largely on the side upon which this evidence is arrayed. If it is corroborative of a previous and carefully formed diagnosis, based on clinical grounds, the question may be considered as settled. On the other hand, but little weight should be attached to any microscopic testimony which contradicts a well-founded clinical diagnosis of malignancy, a circumstance, of course, which occurs but very rarely. If, however, the state of the case is reversed, the microscope declaring for malignancy, whether the clinical evidence to the contrary be doubtful or positive, there can be no doubt but that its testimony is in such a case of much more value than that of any symptom, or probably than any group of symptoms, and the wisest course is to call the disease malignant and treat it as such. We should not fail to remember that while a certain definite structure is probably infallible evidence of inherent malignancy, physiologic resistance, or even less understood conditions of environment, may explain the apparently benign tendencies of some essentially malignant growths; and further, that those adverse conditions may, for aught we know, become at any time so modified as to allow the tumor to manifest the most baneful characteristics.

It is probably true that sarcoma of this region manifests, on the whole, a less malignant tendency than when occurring elsewhere. Certainly, though usually considered one of the most important manifestations of malignancy, the occurrence of metastasis is an extremely rare event. I have found it mentioned but 3 times. In two of those cases the cervical glands were involved, in the other—Warthin's case—there was universal metastasis, including even the formation of a free sarcomatous mass in the right ventricular cavity of the heart. The ultimate history of 45 cases of the present series does not appear in the records. Of the remaining 105 cases, 62 patients are stated to have recovered. In only 28 of these 62 cases, however, does the history subsequent to treatment extend over a period of longer than 6 months' duration, a circumstance which renders the statement of recovery in the remaining 34 cases almost useless. The average duration of life in the fatal cases appears to be about 2 years from the first appearance of symptoms.

Apart from surgical measures, the only treatment worthy of consideration is that by toxins, either of *Streptococcus erysipielatis* or mixed toxins of *Streptococcus erysipielatis* and *Bacillus prodigiosus*—Coley's fluid. In none of the cases of the present series, however, in which this treatment was tried was there any noticeable improvement, even when marked reactions were obtained. This corresponds with my experience in a case of sarcoma commencing in the alveolar process of the right superior maxillary bone, and secondarily invading the antrum and nasal fossa. Nevertheless, I am inclined to attribute the retardation of growth in my own third case to the attacks of erysipelas. Plicque and others strongly condemn any attempt at intranasal operation on malignant neoplasms, on the ground that it is nearly always impossible to eradicate the growth completely through the natural channels and that such ineffectual interference is likely to become an excitant to greater malignancy. The cases under consideration bear on this question as follows: Out of 48 cases stated to have been submitted to radical operation, the subsequent history was unknown, or unreported, in 13. Nineteen patients recovered and were free from recurrences for a variable

period. In 16, recurrence or death took place. The percentage of cures thus obtained by radical external operation was 39.58. In 64 cases, in which the patients were treated by intranasal operation, the figures stand thus: Result not stated, 8; recovery, 35; recurrence or death, 21; percentage of recoveries, 54.68. The weight of this evidence in favor of intranasal operation is increased by a consideration of the comparatively large number of cases in which the result of radical operation is not stated. While on the other hand it is probably true that the cases submitted to radical external operation are usually more advanced and more hopeless than those in which the milder measures are adopted, the fact that over 54% of the latter are cured surely justifies the adoption of those milder measures, in selected instances at least. It is noticeable, further, that some severe and far advanced cases, advanced even to the stage of considerable external deformity, *e. g.*, my own second case, are cured by intranasal operation. The second objection, viz., the possibility of exciting the growth to greater malignancy, finds little justification in the records of the series, inasmuch as even manifestly incomplete operations appear almost invariably to have prolonged life and alleviated suffering. In any event there can certainly be no justification for a primary external operation on a small pedunculated sarcoma with a point of origin in an easily accessible region. In such instances at least the cold wire snare should invariably be the instrument of first choice, and is commonly the only instrument necessary for the complete eradication of the growth.

Out of 4 cases of the series in which ligation of the carotid of one or both sides was resorted to, there was marked improvement in 3. The other patient died as a result of the operation. Dawbarn's procedure of exsecting the external carotid artery appears to be an improvement on simple ligation, and gives promise of at least rendering operable many otherwise inoperable growths.

Appended is a list of the cases not included in the collection of Bosworth and Gibbs. Gibbs' collection, which included all of Bosworth's cases, may be found in the *New York State Journal of Medicine* for January, 1902.

TOXEMIA ASSOCIATED WITH TUBERCULOSIS OF THE CERVICAL LYMPHATIC GLANDS, WITH REPORT OF A CASE.*

BY

ARTHUR W. ELTING, M.D.,

of Albany, N. Y.

Attending Surgeon to the Albany Hospital; Attending Surgeon to the Child's Hospital.

In the voluminous literature of tuberculosis there are but few references to the so-called toxemia resulting from a localized focus of infection and due to the products of the life and growth of the tubercle bacilli alone. In most instances when the toxic phases of the disease have been especially pronounced it is safe to assume that the disease was more or less generalized and was in reality a miliary tuberculosis, or else there was a secondary infection superadded. The following case, which was referred to me some time since by Dr. W. H. Murray, of Albany, N. Y., illustrates a phase of surgical tuberculosis upon which but little emphasis has hitherto been laid:

W. W. G., aged 26, consulted me March 7, 1903, for an enlargement of the right side of the neck. The family history was negative in every respect. The patient had had the usual diseases of childhood, but otherwise had excellent health. He denied all venereal infection and did not use alcoholic drinks. His occupation for several years had been that of a mechanic. Early in December, 1902, a barber had called his attention to a tumor situated on the right side of the neck just behind the angle of the jaw. The tumor at that time was the size of a small pigeon's egg and was of firm consistence, but was not tender or painful. His general health at that time was good and he knew of no cause for the enlargement. The tumor had gradually increased in size, but had enlarged rather more rapidly during the 3 weeks prior to his admission to the Albany Hospital. He had worked steadily until a month before admission to the hospital, when he was compelled to stop work because of a progressive general weakness. His appetite had gradually failed and he had lost between 25 and 30 pounds in weight. He had not had any cough, but there had been marked shortness of breath on the slightest exertion. The bowels were regular and there had been no nausea or vomiting. The patient stated that about 3 weeks before admission to the hospital he had begun to feel feverish at times and had had chilly sensations, with a few night sweats. During the 10 days prior to his admission to the hospital the patient's condition became rapidly worse and his fever continuous, ranging from 101.5° to 104.4°, and his pulse from 100 to 130. Associated with this condition there was a marked prostration, so that the patient was confined to his bed.

On admission to the hospital his condition seemed most critical. His temperature was 103.2°; pulse 120. He was a moderate framed, decidedly emaciated young man. The skin and mucous membranes were extremely pale. The tongue was covered with a heavy, moist coat. The expression was dull and apathetic and he appeared extremely prostrated. The lungs were found to be normal. The heart was somewhat hypertrophied and slightly dilated, and presented the typical signs of a mitral stenosis. The abdomen was symmetric, except that the left costal groove was obliterated. The spleen was markedly enlarged on percussion, and could be seen and felt fully 3 cm. below the left costal margin. The edge was rounded. The liver was not enlarged, and the kidneys could not be palpated. The bones and joints were normal. The reflexes were normal. The right side of the neck presented an extensive tumor mass which was most marked near the sternocleidomastoid

muscle and which occupied a considerable portion of the anterior and posterior triangles. The tumor extended from the top of the right mastoid process to slightly behind the right clavicle. On palpation it was found to be composed of a series of greatly enlarged lymphatic glands. Both the superficial and deep chains of glands were involved. Many of the glands were discrete and could be palpated individually, while others were somewhat matted together. The glands were of rather firm consistence and not at all tender. The skin was freely movable over the glands and of normal appearance. There was no enlargement of the other glands of the neck, nor of the axillary or epitrochlear glands. There seemed to be a very slight enlargement of the left inguinal glands, but none of the right.

An examination of the blood at this time showed the following condition:

Red blood-corpuscles	3,650,000
White blood-corpuscles	3,000
Hemoglobin	75%

The differential count of the leukocytes showed them to be present in the following proportions:

Polymorphonuclear leukocytes	47%
Large mononuclear leukocytes	48%
Small mononuclear leukocytes	5%

The urine was normal in every respect.

The question of diagnosis seemed rather difficult at this time. Because of the character of the enlarged glands, the marked enlargement of the spleen, the blood picture, and the fever, the case was regarded as most probably one of Hodgkin's disease, in which diagnosis both Dr. Murray and Dr. Hun concurred. The patient was growing rapidly worse and it was evident that death would soon occur unless something could be done to relieve the condition. An immediate operation was advised and consented to.

On March 11, under ether anesthesia, through an S-shaped incision, the enlarged glands were carefully excised. The superficial and deep chains of glands were all enlarged and it became necessary to sever the sternocleidomastoid muscle at the junction of its upper and middle thirds to facilitate the removal of the glands, which were quite adherent to the sheath of the vessels. After the removal of all the enlarged glands the severed ends of the sternocleidomastoid muscle were sutured with catgut and the wound closed with a small drain at the lower angle. The patient stood the operation well and exhibited but slight shock.

During the first 24 hours after the operation the patient's temperature ranged from 103.2° to 104.6°, and the pulse from 120 to 140. He received rectal enemas of whisky and salt solution every 3 hours, and 1 mg. (1/30 gr.) of strychnin every 2 hours. His condition, however, at the end of 24 hours was decidedly critical. In the hope of reducing the temperature, ice sponges were given every 3 hours, but with little effect.

The temperature during the second 24 hours after operation ranged from 101.6° to 104.8°; and the pulse from 112 to 128. The rectal stimulation was discontinued and the patient received .3 cc. (5 m.) of the fluid extract of digitalis hypodermically every 4 hours. The ice sponges were discontinued and ice packs every 3 hours substituted. After this the temperature began to fall. At the end of 48 hours after the operation the patient's condition was decidedly improved; the temperature was lower and the pulse of better character.

The temperature and pulse continued to fall during the third 24 hours, until 72 hours after operation it reached 99° and the pulse 90. The patient's condition was greatly improved in every respect. He took nourishment freely and slept well. Practically all of the stimulation was discontinued, as were the ice packs. The patient's convalescence from thence was most satisfactory. The temperature and pulse remained normal and his general condition improved rapidly. He ate and slept well and was able to sit out of bed a week after the operation. The drain was removed from the wound at the end of 48 hours, and the wound healed satisfactorily.

At the time of his discharge from the hospital, 10 days after admission, his general condition was excellent. His temperature and pulse were normal. There was slight induration along the scar, and the action of the sutured sternocleidomastoid muscle was satisfactory. The spleen had decreased greatly in size and could not be palpated, although it was found to be slightly enlarged on percussion.

An examination of the glands removed at the operation was made by Dr. Blumer, of the Bender Hygienic Laboratory, who reported that they presented the typical macroscopic picture of tuberculosis with extensive caseation. There was, however, no tendency to a softening of the caseous material. Tubercle bacilli were demonstrated in this caseous material, but they were comparatively few in number. Cultures from the glands were sterile. The microscopic picture was that of a typical tuberculosis of the lymphatic glands.

The patient's subsequent history was uneventful. He gained rapidly in weight, and June 10, 1903, 3 months after the operation, he weighed more than he ever had in his life. His general health was excellent. The scar was perfect in every respect. The action of the sutured sternocleidomastoid muscle was normal and the patient stated that he had never felt so well in his life. There was no evident enlargement of any of the

* Read before the Medical Society of the State of New York, January 26, 1904.

lymphatic glands of the body and the spleen could not be felt, the area of dulness being normal in extent. An examination of the blood at this time showed the following condition:

Red blood-corpuscles	4,550,000
White blood-corpuscles	6,000
Hemoglobin	86%

A differential count showed the relative proportions of the leukocytes to be normal.

January 3, 1904, the patient was again seen, and he stated that his health had remained excellent since the last examination in June. Physical examination at this time showed him to be absolutely normal in every respect, except for the signs of mitral stenosis already referred to.

Of especial interest in this case was the blood picture, a hypoleukocytosis of 3,000, with 48% of large mononuclear leukocytes, conditions which would suggest Hodgkin's disease rather than tuberculosis, and which returned to normal after the removal of the glands. That the process should have remained localized in the glands of one side of the neck and that no subsequent recurrence of the disease occurred, seems, indeed, striking in view of the fact that the infection was of such a virulent character.

Of importance, also, is the fact which has frequently been demonstrated, that section of the sternocleidomastoid muscle, with subsequent suture, can be safely performed with every probability of the restoration of perfect function. This procedure greatly facilitates the removal of the cervical lymphatic glands when they are extensively diseased, and should be more frequently adopted.

After a careful search of the literature of tuberculosis, I have been unable to find reference to a similar case in which so profound a toxemia has developed in association with a localized focus of tuberculosis of the lymphatic glands, and in which so rapid a recovery followed the removal of the focus. There seems no other logical explanation of the grave symptoms than that they were caused by the absorption of toxins from the tuberculous glands, and the presence of these toxins in the circulation was undoubtedly the cause of the markedly enlarged spleen, which must have been of the nature of an acute spleen tumor. The extremely desperate condition which followed immediately after the operation, and which lasted nearly 48 hours, was in all probability due to the introduction of a large amount of toxin into the circulation through the manipulation of the glands, incident to their removal. The source of the toxin having been removed, and that present in the organism having been eliminated, a rapid convalescence naturally ensued.

ACQUIRED HYDROPTHALMUS.*

BY

EDWARD STIEREN, M.D.,

of Pittsburg, Pa.

Assistant in Ophthalmology and Otolaryngology, Western Pennsylvania Medical College; Ophthalmologist and Otolaryngologist Passavant Hospital and McKees Rocks General Hospital.

Congenital glaucoma, infantile glaucoma, hydrophthalmus, buphthalmos, *totale ektasie der sclera*, are terms used to express a pathologic ocular condition characterized by a symmetric enlargement of the eye in all its diameters.

The affection appears at birth or shortly after, having its origin in intrauterine life. It usually involves both eyes,¹ progresses slowly and nearly always terminates in blindness.

The first symptom observed is the characteristic cloudiness of glaucoma in the cornea.² The child will exhibit more or less photophobia and appear to have

pain in the eyes. Then there usually ensues a period in which the eyes are quiet and free from inflammation only to be followed in a few days or weeks by a repetition of the former symptoms. There is marked increase of intraocular tension; the anterior chamber becomes deep, the pupil dilated and the iris tremulous.

On account of the yielding character of the tunics of the eyeball at this period of life and with the coexisting inflammation in the sclera, the increased internal pressure causes the eye to enlarge in all directions and the sclera becomes thinned and bluish-white in color owing to the uveal pigment showing through. The cornea likewise participates in the enlarging process and the optic disc becomes deeply excavated.³

The etiology of this affection is not thoroughly understood. An intrauterine iridokeratitis with increased intraocular tension in a certain proportion of cases, congenital defective development at the filtration angle in others,⁴ are the most plausible reasons that can be given.

That the condition can, however, occur in later childhood and as a result of traumatism the following report illustrates.

Sarah K., aged 11, was brought to me by her parents with this history. When about 8 years of age, while jumping a knotted rope swung by two companions, she was accidentally

Actual size.

struck in the left eye with the knot. Considerable inflammation and pain in the eye followed this injury, with exacerbations and remissions of the symptoms for the space of about a year, at the end of which time the eye began to grow larger, sight being completely lost soon after. For the next 2 years the eye was comparatively free from pain, but the disfigurement caused by the continually enlarging eye as it protruded more and more became most marked, and for this one symptom relief was sought.

Examination revealed the enlarged globe, almost immovably fixed in the orbit, over which the lids glided freely. Tension was slightly reduced, light perception absent, cornea hazy and the pupil bound down to a cataractous lens.

Enucleation was performed without incident save that the optic nerve was torn from its scleral attachment when the enucleation scissors were introduced, due to the thinned and softened condition of this tissue. The vitreous, being fluid, escaped through this opening.

In the fresh state the eyeball measured anteroposteriorly 32 mm., equatorially 30 mm., while the diameter of the cornea averaged 16 mm.

SPECIAL ARTICLES

THE USE AND ABUSE OF THE IMAGINATION IN THE EXPERIMENTS AND OBSERVATIONS IN MEDICINE.¹

BY

JOHN C. HEMMETER, Med. et Philos. Dr.,
of Baltimore, Md.

Professor of Physiology and Clinical Professor Diseases of the Digestive Organs, University of Maryland, Baltimore.

This Association was founded for the encouragement and diffusion of medical learning in the pathology of the digestion and metabolism. Its creed is very simple, requiring in the new member only will and devotion. It is our business to study the works of nature, and particularly of abnormal nature, as manifested in the human body, by observation and experiment, and it is our duty to conform our conduct to nature's laws. We believe that upon this line of investigation lies the true road of progress for scientific medicine. We do not wish individually to impose our ideas on others, but prefer to leave them to the operations of reason and judgment and in this sense we are free among ourselves.

If a brother go astray we let him alone, feeling sure that time will lead him back to the truth. Cicero tells us that time overthrows the opinions of men, and confirms the decisions of nature. With full confidence in this sentiment let us go on in our work? An effort should be made to arrange an occasional symposium on the same subject, that is, let the same subject-matter be discussed from the clinical as well as the surgical side, by reporters of that special meeting. Surgeons and clinicians do not meet often enough to discuss the borderland between medicine and surgery. Then those of a more scientific turn of mind, the lovers of physiology and pathology, should arrange with the clinical men to discuss subjects of mutual interest. For example, the diseases of metabolism, diabetes, obesity, uric acid diathesis, pancreatic and hepatic diseases can only be thoroughly ventilated in this way. Such discussion could be arranged between two reporters of a meeting, or by a motion a special subject could be agreed upon for general discussion. Considerable instruction should result from such conferences, for we have many clever thinkers in this Association, and latent convictions have often only been brought out during a heated and interesting debate.

Great differences exist among medical men. We have general practitioners and medical men of research and experimental philosophers. This imposes upon us the necessity of enforcing a degree of selection in the choice of our new members. I cannot become reconciled to the thought that this union of knowledge and sentiment should ever be disbanded after so many years of fruitful and blessed activity. To you we leave the duty to perpetuate the union of scholarship and good fellowship. It is self-evident that we cannot accomplish our aim without criticism, but critical satisfaction has always been submerged beneath the positive elation over the splendid uprising of medical science at the beginning of the Twentieth Century.

There are many infatuations which exercise a kind of tyranny in medicine. To raise personal preferences to the dignity of a creed is not enough. A cult once established, a dogma once accepted—there can be no more freedom from analysis, no more independent criticism, no more permissible dissent. The usual procedure is to give unthinking assent. Mental indolence is, of course, at the bottom of this fashion. It is easier to accept an opinion than to form one. Never has the tendency to slavish partisanship been more general nor despotism of ready-made judgments more absolute than in these times of pretended scientific emancipation and so-called individualism.

It is dangerous to classify imperfectly-known data under general theories, and sound progress of science requires of us to be clear at every moment which elements in the system of science are hypothetic and which are the limits of that knowl-

edge which is obtained by direct observation.¹ There are few students who possess that cold enthusiasm for truth which enables them to be always clearly conscious of the sharp line between attractive theory and observation acquired by hard and earnest work.

Speaking of the ebb of intellectual force, which we all from time to time experience, Mr. Bain² says: "The uncertainty where to look for the next opening of discovery brings the pain of conflict and the debility of indecision." These words have in them the true ring of personal experience. The action of the investigator is periodic. He grapples with a subject of inquiry, wrestles with it, overcomes it, exhausts both himself and it for the time being. He breathes a space, and then renews the struggle in another field. Now this period of halting between two investigations is not always one of pure repose. It is often a period of doubt and discomfort, of gloom and ennui. "The uncertainty where to look for the next opening of discovery brings the pain of conflict, and the debility of indecision."

John Tyndall³ states it is well worth the while of the scientific teacher to take some pains, and even great pains, to make those whom he addresses copartners of his thoughts. But it is by no means easy to clear his own mind in the first place of all haze and vagueness, and then to project into language which shall leave no mistake as to his meaning, and which shall leave even his errors naked, the definite ideas he has shaped. Much is possible to scientific exposition conducted in this way. Even before an audience like the present, it is possible to uncover to some extent the unseen things of nature, and thus to give not only to professed students, but to others with the necessary bias, industry, and capacity, an intelligent interest in the operations of science. Time and labor are necessary to this result, but science is the gainer from the public sympathy thus created.

It appears to be characteristic that every new view or statement in all domains of knowledge is announced with perfect self-assurance, in order to be impressive. And the inclination of human beings to dogma, and the deficient philosophic culture of large circles, has lent encouragement to this custom.

Yet little or nothing of the context of new things can in the strictest sense be proved by observation, and much less by experiment, which pretends to be a high judge of clinical medicine.

I do not desire to make you critically apprehensive by a paradox, but I cannot refrain from suggesting that really nothing can be proved by experience and experiment. Phenomena can be accurately observed, experiments can be precisely executed. One is enabled to arrange experience and experiment in a certain order, one can deduct one phenomenon from another. A certain, definite circle of knowledge may be established. One can even elevate one's views to a degree of certainty and completeness, and that is accomplishing much.

However, deductions in the minds of others are formed by everyone for himself. As far as one goes with his logic, one cannot prove anything by it. Everything concerning the opinions about things belongs to the individual—and we know very well that convictions do not depend upon insight but upon the will. Nobody grasps or understands anything except that which his will concedes. In knowledge, as well as action, the foreknowledge or prejudice decides everything—and prejudice, as its name indicates, is a judgment before investigation.

Philosophers may be right in affirming that we cannot transcend experience; but we can at all events carry it a long way from its origin. We can also magnify, diminish, qualify and combine experience, so as to render it fit for purposes entirely new. We are gifted with the power of imagination, and by this power we can lighten the darkness which surrounds the world of the senses.

John Tyndall³ says:

There are Tories even in science who regard imagination as a faculty to be feared and avoided rather than employed. They had observed its action in weak vessels, and were unduly impressed by its disasters. But they might with equal justice

¹ President's address, American Gastroenterologic Association, Washington, D. C., May 14, 1903.

² Role of Hypotheses in Medical Research: W. Ostwald.

³ Bain's Logic.

³ Scientific Use of the Imagination.

point to exploded boilers as an argument against the use of steam. Bounded and conditioned by cooperant reason, imagination becomes the mightiest instrument of the physical discoverer. Newton's passage from a falling apple to a falling moon was, at the outset, a leap of the imagination. When William Thompson tries to place the ultimate particles of matter between his compass points, and to apply to them a scale of millimeters, he is powerfully aided by this faculty. And in much that has been recently said about protoplasm and life, we have the outgoings of the imagination guided and controlled by the known analogies of science. In fact, without this power, our knowledge of nature would be a mere tabulation of coexistences and sequences. We should still believe in the succession of day and night, of summer and winter; but the soul of force would be dislodged from our universe; causal relations would disappear, and with them that science which is now binding the parts of nature to an organic whole.

All the facts which we have considered, the liability to error in whatever direction we may go, the infirmity of our minds in their reasoning power, the fallibility of witnesses and experimenters, lead the scientist to be specially sceptical with reference to any statement made to him or any so-called knowledge that may be brought to his attention. Professor H. A. Rowland made the following statement in an address made shortly before his death:

The facts and theories of physical science are so much more certain than those of history, of the testimony of ordinary people on which the facts of ordinary history or of legal evidence rest, or of the value of medicine to which we trust when we are ill—indeed, to the whole fabric of supposed truth by which an ordinary person guides his belief and the actions of his life, that it may seem ominous and strange that what I have said of the imperfections of the knowledge of physics is correct. How shall we regulate our minds with respect to it? There is only one way that I know of, and that is to avoid the discontinuity of the ordinary, indeed, the so-called cultivated legal mind. There is no such thing as absolute truth and absolute falsehood. The scientific mind should never recognize the perfect truth or the perfect falsehood of any supposed theory or observation. It should carefully weigh the chances of truth and error, and grade each in its proper position along the line joining absolute truth and absolute error.

If this latter injunction is followed out very little room is left for the use of the imagination in the solution of medical problems, and even when employed in a controlled and limited extent, its yieldings must always be submitted to the test of repeated demonstration, if possible by experiment. When imaginative power was left to develop questions of research unaided, it yielded only hypotheses, and these are the curse of medicine.

The ordinary crude mind has only two compartments, one for truth and one for error, indeed, the contents of the two compartments are sadly mixed in most cases; the ideal scientific mind, however, has an infinite number.¹ Each theory or law is in its proper compartment indicating the probability of its truth. As a new fact arrives, the scientist changes it from one compartment to another in order to keep it, if possible, in its proper relation to truth and error. Thus, the fluid nature of electricity was once in a compartment near the truth. Faraday's and Maxwell's researches have now caused us to move it to a compartment nearly up to that of absolute error.¹

So the law of gravitation within planetary distances is far toward absolute truth, but may still need amending before it is advanced further in that direction.

The ideal scientific mind, therefore, must always be held in a state of balance which the slightest new evidence may change in one direction or another. It is in a constant state of scepticism, knowing full well that nothing is certain. It is, above all, an agnostic with respect to all facts and theories of science as well as to all other so-called beliefs and theories and cannot yield to temptations held out by processes of imagination. If the foremost American physicist thought it his duty to caution against the scientific absolutism of today in a domain to which the most precise and accurate methods are applicable, it is evident that the same caution is more directly applicable to researches in medicine, to which methods of equal accuracy are not applicable and in which more liberty is as a rule conceded to the power of imagination.

Care should be had lest this Association drift into that state which is commonly known as a "mutual admiration society."

¹ H. A. Rowland, loc. cit.

Fair-minded and conservative criticism is one of the most edifying and instructive forms of debate. Nine-tenths of all medical publications of the present day are simply compilations of scientific facts, to which no individual interpretation is added. Such compilations have in reality very little value unless the author is capable of associating with them conservative critical judgment, based on broad experience. Let us hope that the reports of the American Gastroenterologic Association will more and more become precise and accurate statements of critically digested and tested truths, in which nothing is stated simply on the authority of someone else, without having been again thoroughly considered and revolved in the brain of the reporter, and worked up by a systematic plan and order. At no point in the report to a representative scientific body should there be any doubt of the logical connection of the various parts of the report, and one argument should be logically succinct upon another. I have stated this because my personal experience has been that quite a number of reports have not given evidence of these qualities. They have been devoid of those evidences of mental digestion on the part of the writer, and of logical criticism which are the most unfailing proofs of broad experience, keen and conservative judgment, and a good and sane heart that always wishes and works for the best.

THE WORLD'S LATEST LITERATURE

Journal of the American Medical Association.

March 26, 1904. [Vol. XLII, No. 13.]

1. The Dietetics of Atonic Dilation of the Stomach, Based on a Study of the Physiology of Gastric Movements. FENTON B. TURCK.
2. The Mathematics of the Diabetic Diet. ALFRED C. CROFTAN.
3. The Relation of Nature's Provision for Heart Stimulation and Control to the Use of Cardiac Drugs in Acute Disease. LOUIS FAUGERES BISHOP.
4. Obstruction and Consequent Distention the Cause of Appendicitis, as Proved by Cases and by Experimental Appendicitis in Dogs. C. VAN ZWALENBURG.

1.—Dietetics of Atonic Dilation of the Stomach.—F. B. Turck has demonstrated by animal experimentation that strong HCl, peptones, albumoses, starch, etc., show no appreciable effect on movements, while distention with air or water immediately excites peristalsis. If the air or water is forced into a bag within the stomach so that it will return promptly the resultant contractions after return are more numerous and vigorous. Chemic stimulation may cause opening or closing of the pyloric orifice, but tension on the walls is more important in producing stomach movements. The writer reviews the principles on which tension rests. In exhaustion, fatigue and atony the same law exists, except that increased stimulation and longer periods of rest are required. Mechanical work is divided into (1) distention with food, (2) expulsion, (3) relaxation. Increased work may be due to increased load within the stomach or increased resistance at the pylorus. If this work passes beyond physiologic limits, atony and dilation follow. Increased quantity does not proportionately increase the sojourn of food in the stomach. In pyloric obstruction, removal of the obstruction is the only treatment. In other cases rational diet must be ordered. Frequently repeated small meals are contraindicated. A large meal increases peristalsis, hastens expulsion, prolongs the period of rest, allows ample drainage, thus preventing bacterial growth, and increases appetite. [H.M.]

2.—Mathematics of the Diabetic Diet.—A. C. Croftan believes that lack of accuracy is the cause of death in many cases. The normal adult needs from 30 to 35 calories a day per kilo of body-weight. With loss of sugar in the urine the average diet will not furnish this. One can calculate what proportion of the deficit is made good from the albumin and fat of the tissues respectively by determining the intake and output of nitrogen, and the amount of sugar in the urine. The writer illustrates this statement. It is necessary in each case to determine the exact tolerance of the body to carbohydrates. Occasionally glycosuria is due to too much sugar in the food, but generally to insufficient power in the organism to destroy the normal amount. Glycosuria is mild when it disappears on removal of carbohydrates, does not reappear when small quan-

tities are again eaten, and when the food albumin need not be reduced. In the medium type, food albumin must be reduced till less than 18 gm., but more than 10 gm. of N appears in the urine. The form is severe if so much albumin must be withdrawn that less than 10 gm. of N appears in the urine. [H.M.]

3.—Heart Stimulation.—L. F. Bishop thinks the term heart regulators should be substituted for heart stimulants in classifying many cardiac drugs. Stimulants are indicated only in sudden emergencies and the best stimulants, as ammonia, ether, and nitrite of amyl, are poor regulators. Failure of the heart most frequently takes place in the direction of increased rapidity. This is combated by measures influencing vitality, thus restoring inhibition, as by the use of strychnin, hydrotherapeutics, nutritive food, and above all, of sleep and the removal of exhausting influences. [H.M.]

4.—Obstruction and Consequent Distention the Cause of Appendicitis.—C. Van Zwahlenburg reports at length his experiments on dogs and a study of several cases of appendicitis in human beings, leading to the following conclusions: Simple infection does not account for the suddenness of the attack nor early severity of the pathologic changes in acute appendicitis. The evident interference with the blood supply is best accounted for by an increased intraappendicular pressure. Simply injecting bacteria into the appendix will not produce appendicitis unless used in abnormal amounts and virulence. Subperitoneal ligation of the appendix with a simple ligature cannot be made sufficiently permanent to produce a general infection of the appendix, typical of appendicitis in the human being. Experiments in dogs show that hydraulic pressure equal to the arterial tension maintained within the lumen for a short time is promptly followed by typical appendicitis. The blood supply in an extremity may be cut off with impunity for hours, but in the appendix, bacteria begin an infection at once, their entrance into the tissues being facilitated by the opening of normal and traumatic avenues by the very distention which cuts off the circulation. Boston Medical and Surgical Journal.

March 10, 1904. [Vol. CL, No. 10.]

1. Blood-pressure Observations in Surgical Cases: Report of the Committee on Research for the Division of Surgery, Harvard Medical School, January, 1904, at the Boston City Hospital. WILLIAM E. FAULKNER, JAMES S. STONE, FRED T. MURPHY. Summary of Results. Committee on Surgical Research.

1.—Blood-pressure Observations in Surgical Cases: Being a Report of the Committee on Research for the Division of Surgery.—In February, 1903, a letter was sent out by the committee on surgical research of the Harvard Medical School to the surgeons to the Massachusetts General, the Boston City Hospital and the Children's Hospital, asking that a report be made after due trial with the Riva-Rocci apparatus in surgical cases. The present article is devoted to a report from these 3 hospitals, together with comments thereon made by the committee. William E. Faulkner compiled the report from the Boston City Hospital, and his conclusions are that in the general run of surgical cases blood-pressure observations do not point out dangers that could not be foreseen by observations of the patient's pulse, respiration and general condition, but that in head injuries a high blood tension may be an indication of brain compression when the pulse would not lead us to suspect such a condition. Dr. James S. Stone compiled the report from the Boston Children's Hospital and his conclusion is as follows: Ether causes a rapid rise in the blood-pressure as indicated by the Riva-Rocci apparatus. This rise is followed by a very much slower fall in the pressure. Ordinary operative procedures seem sometimes to increase the pressure slightly. With the establishment of shock the pressure is lowered, but other signs of shock, the more rapid pulse, the more feeble respiration, the cold, clammy skin, are noted earlier during operations than is a drop in blood-pressure. Conversely, patients practically pulseless at the wrist can withstand operations. Crying, vomiting, retching, struggling, or changes in position affect the blood-pressure so much more than ordinary operative procedures as often to render pressure charts practically valueless, unless all these circumstances are noted. Dr. Fred T. Murphy

compiled the report from the Massachusetts General Hospital in the following conclusions: These statements are based on the results of blood-pressure observations which were made on 100 surgical cases, including 28 cases of head injury. The Riva-Rocci manometer was employed in every case. The blood-pressure in the majority of cases confirmed the estimate of the clinical condition of the patient obtained from the pulse, temperature and other physical signs. Deductions regarding the clinical condition drawn from the blood-pressure observations did not agree in a certain number of instances with the conclusions based upon the results of the routine clinical observations. The subsequent course of the cases proved the blood-pressure readings to have been misleading. The blood-pressure observations did not in any case show facts that proved to be of importance in determining the diagnosis, treatment or prognosis which could not be obtained in the routine methods of clinical examination. The effect of the common subcutaneous stimulants was not marked. Normal salt solution, as a rule, raised the blood-pressure, the maximum rise being reached with the administration of the first pint. The increased pressure was maintained for a variable period, usually about 30 minutes. Cases of head injury, while not always typical and uniform in the reaction, as shown by the blood-pressure readings, seem to offer a field in which blood-pressure observations may prove to be of material assistance to the observer. The committee comments at length upon these reports and summarizes its conclusions as follows: It may be said that the value of Riva-Rocci apparatus in determining the blood-pressure in surgical patients is limited to a comparatively small number of cases. The conditions of cerebral compression and of surgical shock, produce the most marked and definite alterations in the blood-pressure. When these conditions are present and other confusing causes of alteration in the blood-pressure are eliminated, the value of the blood-pressure determinations, as an indication for or against operation, is increased. Under other circumstances the value of these observations is at present not apparent. The adoption of blood-pressure observations in surgical patients does not at present appear to be necessary as a routine measure. [A.B.C.]

Medical Record.

March 26, 1904. [Vol. 65, No. 13.]

1. Is Iodid of Potassium a Specific in Lobar Pneumonia? H. ALT-SHUL.
2. Report of a Case of Kidney Decapsulation, with Some Observations on the Operation. A. G. GRUNWELL.
3. Cases of Urethral Stricture and their Management. JAMES PEDERSEN.
4. Some Observations while Serving in the Philippines. J. A. GUTHRIE.
5. Value of Total and Differential Leukocyte Counts During the Course of Typhoid Fever. HENRY A. HIGLEY.
6. A New Sign of Basilar Meningitis. G. W. SQUIRES.

1.—Is Potassium Iodid a Specific in Lobar Pneumonia?—H. Altshul reports the results of 62 cases of his own and others of his colleagues amounting together to 250 treated by potassium iodid with a mortality of less than 1%. He discusses the action of the drugs with especial relation to the morbid conditions found in pneumonia. It antagonizes the infection, being antiseptic in solutions of 1 to 4,000, while carbolic acid needs a solution of 1 to 333. It diffuses more rapidly and is free from toxic and dangerous effects. It greatly increases the activity of the glands and the greater the hyperleukocytosis, the more favorable the course of the disease and the drug is without the disadvantages and dangers of the protalbumoses, spermin, nucleins, pilocarpin, etc. There is a definite connection between leukocytoses and the blood's alkalinity, and there is no agent so effective in alkalizing it as the potassium salts. The vasodilator action of potassium iodid is of great importance in lessening arterial tension, thus reducing the burden on the heart and by this means also counteracting the friction from the viscosity of the blood. It directly stimulates the circulation through its action on the heart vessels. The diuresis induced also relieves the heart as well as eliminates the toxins. The antipyretic effect is due to the vascular dilation and diaphoresis. The respiratory rhythm is slowed. Liquefaction and absorption of inflammatory products diminish cough. In all the cases the termination was by lysis, duration was not shortened, the temperature never exceeded 104° when treatment began early;

complications never occurred. The initial dose is 10 gr. to 15 gr. increased by 5 gr. or 10 gr., according to the severity of the case, every 2 or 3 hours day and night until defervescence, the regularity of the heart, determined by auscultation, being the guide. In irregularity, strychnin should be given. Many patients take from 1,000 gr. to 1,500 gr. of ioddid daily. Unfavorable results are due to faulty methods. [H.M.]

2.—Operation upon the Kidney.—A. G. Grunwell, surgeon U. S. N., reports that a robust man in the navy complained of symptoms that could be attributed to renal lithiasis, movable kidney, or some other pathologic renal condition. Operation was performed and the enlarged friable kidney opened but no stone was found. The capsule of the kidney was slit open from pole to pole and each half dissected free from the kidney substance for some distance, rolled upon itself and sutured to the lumbar fascia and muscles of the wound. The patient made a good recovery and was relieved from his symptoms, which the author believes were due to a congested and chronically inflamed kidney. The author believes that our knowledge concerning congestive and inflammatory conditions of the kidney needs much addition and the subject should be thoroughly investigated with especial reference to operative treatment for its relief. He believes that the operation above described is preferable to Edebohls' renal decapsulation and he claims for it the following advantages: 1. The great ease with which it can be performed as compared with the complete removal of the capsule. This is no unimportant item where the condition of the patient makes rapidity and the avoidance of much handling of, or tension on, his kidney imperative. 2. The kidney is fast in the wound, where it can be seen without difficulty and is accessible in case of hemorrhage, either immediate or secondary. [A.B.C.]

3.—Urethral Stricture and Its Treatment.—James Pedersen reports a series of cases, discusses the proper management, the complications, and summarizes his conclusions in part as follows: Copious irrigation of the penile urethra from the meatus with a solution as warm as the patient can bear, is advised before and after instrumentation until the stricture has been dilated beyond the danger of retention from reactionary swelling. Similar irrigation, or an instillation or irrigation of silver nitrate, protargol or argyrol, is to be practised whenever blood appears after instrumentation. The filiform guide and tunneled instruments are dispensed with as soon as a 20 F. ordinary sound can be passed to the bladder with fair ease. Exceptionally the filiform guide may be dispensed with at 18 F.; but, if the canal through the stricture is tortuous, or if there is a pocket or an old false passage, a sound of smaller caliber than 20 F., unless very blunt, is dangerous except in skilled hands. The bladder is treated so long as there is evidence of cystitis or urethrocystitis. Specific treatment of the urethral mucous membrane with silver nitrate solutions is begun as soon as a caliber of 18 F. or 20 F. has been reached, and is continued, combined with dilation, until the tissues have been made as near normal as possible under the conditions present. [A.B.C.]

4.—Observations of a Surgeon in the Philippines.—J. A. Guthrie, Surgeon U. S. A., writes an interesting paper recounting his observations of the Philippine Islands. He calls attention to the remarkable variety and extent of skin diseases as observed in that country; he likewise directs attention to the number of vermin and insects that annoy and depletes the inhabitants and soldiers. Investigation of the cause of the sudden exhaustion of marines in the Samar campaign showed the cause to be a species of land leech which attaches itself to the legs of soldiers and sucks the blood without causing pain. "Tuba," a beverage made in a crude way by the Filipinos, is practically a decoction from insects, and is nauseating and toxic to white men. "Bino" is another so-called wine, which is manufactured from various substances, and is likewise unwholesome. Specific directions are given to those contemplating a residence in the Philippines, with particular reference to food, avoidance of the sun's rays in the middle of the day, and the abstention from alcoholics and stimulating foods. General directions as to hygienic living, and the character of the diet most suitable to white men, etc., are given. [A.B.C.]

5.—Value of Total and Differential Leukocyte Counts in Typhoid.—H. A. Higley reports investigations showing that so long as typhoid infection remains pure the characteristics of the total and differential counts peculiar to this disease are maintained. In complications these are altered, this alteration preceding the clinical picture of the complication. Therefore, frequent and careful counts are of great value. [H.M.]

6.—A New Sign of Basilar Meningitis.—G. W. Squires has noticed invariably, and frequently as early as the fourth or fifth day, according to the severity of the attack, a rhythmic dilation and contraction of the pupil. The child's head should be placed between the physician's knees, face upward, with the body supported on the bed or by the nurse. He should grasp the sides of the head and produce gradual and forcible extension on the spinal column. As the head is brought back the pupils dilate. Upon flexion they contract so that when the chin is forcibly brought to the manubrium the pupils are well closed. [H.M.]

New York Medical Journal.

March 19, 1904. [Vol. LXXIX, No. 12.]

1. Medical Education. WILLIS G. MACDONALD.
2. The Dangerous (?) Operation of Uterine Curetment. DANIEL H. CRAIG.
3. Appendicitis in Young Children. JOHN F. ERDMANN.
4. Postoperative Pneumonia, With Report of a Case. LAWRENCE E. HOLMES.
5. The Inaccuracy of the Common Spoon as a Milk Sugar Measure in the Home Modification of Milk. D. J. M. MILLER.
6. Tertiary Syphilis of the Nose and Pharynx. (Concluded.) W. SCOTT RENNEE.

2.—Uterine Curetment.—D. H. Craig, while highly commending certain portions, criticises other portions of an article by Dr. Von de Warker in the *New York Medical Journal* of October 10, 1903, entitled "The Dangerous Operation of Uterine Curettement." The author does not agree that it is right to characterize the operation of uterine curetment as dangerous in the abstract, or in the hands of those competent to undertake the performance of any surgical procedure. He says that the greatest danger incident to curetment, taking thorough modern asepsis for granted, is perforation of the uterine wall. He is not in favor of tamponing the uterine cavity for he says no matter how strenuous the effort, it is probable that absolute asepsis is never achieved. The tamponing of the cavity with gauze immediately after a curetment and while the abraded surfaces are still the site of more or less abundant hemorrhage, furnishes a mesh in which the blood will clot and remain within the cavity, instead of draining away by simple force of gravity. This blood clot presents an admirable culture medium upon which the relatively few organisms present may rapidly multiply. It is far more rational, thoroughly to clean the cavity during the operation and then to leave the blood and exudates free to drain through an amply dilated cervix thus tending to wash away organisms. It is wisest to avoid douches of any kind for the first 48 hours, or until the cervix has had time to retract so far as to leave little possibility and no liability of washing material from the vagina into the cervical or uterine canal. [C.A.O.]

3.—Appendicitis in Children.—J. F. Erdmann considers the symptomatology and operative and postoperative treatments of appendicitis in children not over 10 years. He operated in 22 of 29 cases with 2 deaths. All the cases were acute. There were 14 cases of gangrene and perforation; 7 cases with foreign bodies, 4 cases included under foreign bodies containing from 6 to 30 pinworms each. The appendix was removed in every instance. In 14 cases drainage was instituted. These were not in each instance the 14 cases of perforation and gangrene, as some of the latter were closed. In the 7 cases not operated upon, operation was not considered advisable, owing to the almost moribund condition of the patients when seen. The incisions made were those of McBurney in 16 cases, and either the Kammerer or split rectus in the remainder. The stump was inverted after the method of Dawbarn 4 times, and in the remaining 18 cases the stumps were tied off and cauterized with pure carbolic acid. When free pus of the serous variety is present in the general cavity he sponges the peritoneal cavity as dry as possible and closes the wound without drain. When gangrene of the appendix and suspicious mesoappendix are present, he drains for from 24 hours to the time required, as

shown by the discharge, or by temperature chart and pulse. A movement of the bowels is desirable in the first 24 hours following operation, and it is his custom to introduce $\frac{1}{10}$ of a grain calomel triturates as soon as the vomiting ceases. [C.A.O.]

4.—Postoperative Pneumonia.—L. E. Holmes, says that it is much more correct to speak of postoperative pneumonia than it is to speak of anesthesia or ether pneumonia, for statistics show that pneumonia following operations was as frequent, or more so, before the days of anesthesia, as at the present time; and also, that it is as frequent now (at least after some kinds of operations), when local anesthesia is used for major operations, as when a general anesthesia is employed. A general anesthetic does not materially increase the danger of pneumonia following operations if the lungs are in a healthy condition. He says that if pneumonia is more liable to follow the use of ether than it is that of chloroform, which is at least a question, the difference is so slight that it does not begin to counteract the much greater danger with which the administration of the latter is associated. We must have a pure drug, and see that the inhaler, or whatever we use in its place, is perfectly clean. The care with which the anesthetic is given is of great importance. In order to avoid hypostatic congestion, especially if there is any tendency in that direction, the patient's position should be changed as soon as possible after the operation. [C.A.O.]

8. Indicators in Gastric Analysis: With Special Reference to Tropaeolin OO. A. L. BENEDICT.
9. Physiologic and Clinical Aspects of Hydrotherapy: With Its Special Reference to the Treatment of Psychoses. R. D. BAKER.

1.—Pneumatic Tourniquets, with Especial Reference to their Use in Craniotomies.—Harvey Cushing summarizes the dangers of the ordinary tourniquet as follows: Possibility of paralysis, the difficulties of observing the best technic during the application, removal and especially of reapplication, and the pain when no general anesthetic is administered are all familiar drawbacks to the common form of elastic tourniquet. Instead of the older forms of the tourniquet, he suggests the use of a pneumatic tube, which is a modification of that used with the Riva-Rocci apparatus, and the main modification consists of the rubber tube being broader and made of more distensible rubber and of a quality that will stand boiling. It is inflated with the ordinary foot bicycle pump. It may be used in several different ways; it may be placed about the arm, or forearm, or leg, to limit the circulation in case a local anesthetic is employed for surgical purposes. Its principal use, however, as suggested in the article, is in being placed around the head and inflated to control the circulation of the scalp in craniotomy. During the past year he has used this pneumatic tourniquet in a series of 18 craniotomies and is pleased with the result. He believes it would be useful also in producing artificial congestion in chronic processes, such as joint tuberculosis after the method described by Bier. The author describes in detail his method of performing craniotomy, which is interesting and instructive. [A.B.C.]

2.—Death from Fecal Drowning During Etherization.—Edward H. Goodman reports that a man of 65 was brought into the hospital suffering from an old scrotal hernia which, during the previous 2 days, had become strangulated and greatly enlarged. Those who had observed the patient were unable to state whether the vomiting had been fecal in character previous to his admission into the hospital, though the vomiting was stercoraceous after admission. The patient was in a depressed condition, but operation was urgent, and on the administration of ether, before the patient had so much as lost consciousness and without any previous effort at vomiting, he suddenly became cyanosed and ceased breathing. Efforts at artificial

respiration caused the stercoraceous material to flow through the mouth and nostrils in quantities. A rapid tracheotomy was performed, and the same material instantly flowed out of the tracheotomy wound. The heart continued to beat for 10 minutes after respiration ceased, but artificial respiration, kept up for 30 minutes, failed to resuscitate the patient. The author believes that the case illustrates the contention of Andrews, that ether benumbs the sensibility of the throat, and in case of intestinal obstruction the patient is apt to drown in his own fecal overflow from the stomach, without any effort at vomiting. [A.B.C.]

3.—Saliva: Its Physiology, Chemistry, and Pathology.—Harold M. Hays writes at length upon the physiology and chemistry of the saliva, his dissertation being such as is ordinarily found in the textbooks on this subject. Concerning the pathology of this secretion, he holds that there is a field for investigation that has as yet been poorly explored. It is probable that there is an altered state of the saliva in latent disease in which no other indication of the disease may be found. It is known that deficiency of salivary secretion is often associated with depleted or depraved function of the stomach, and in wasting fevers, likewise, the increased salivation is caused by hyperacidity of the gastric juices. *Fatty saliva* is often associated with a fat necrosis due to some obstruction to the circulation. *Sweet saliva* is an accompaniment of diabetes mellitus. *Albuminous saliva* is exceedingly uncommon. *Bilious saliva* is found in severe cases of jaundice due to cholecystitis, cholelithiasis, or carcinoma of the head of the pancreas. Oftentimes the saliva is not colored, but on chemic examination is found to contain bile salts and bile acids. *Bloody saliva* is of no consequence, as it is usually due to hemorrhage in the nasopharynx or from an ulcer of the stomach, where the other symptoms are of much more importance. The only point is to differentiate it from a hemoptysis. *Uric acid* may be found in the saliva or a uric acid diathesis may alter the saliva. [A.B.C.]

4.—Surgery of the Gallbladder and Ducts.—John F. Erdmann discusses this subject at some length, and reports a series of cases. In his operations he has ceased to dissect out the mucous membrane of a gallbladder previous to drainage, except in cases in which adhesions are very extensive. He is strongly in favor of cholecystectomy. He says the operation has many advantages over that of cholecystotomy, some of which are: No danger of recurrence, no necessity for secondary operation, no soiling of the patient by leakage, etc., more rapid convalescence with less danger of hernia. The operation is one of considerable ease, and when once fairly understood should be done in preference to cholecystotomy, but for the beginner in gallbladder surgery, cholecystotomy is preferable to the more radical operation. As a preliminary to cholecystectomy, and in common duct work, the use of a sand cushion under the back in the upper lumbar region is desirable. After removal of the gallbladder, if no drainage is decided upon, the duct is tied off and treated like the stump of the appendix. If the case is an infected one, drainage is carried down to the stump with a strip of iodoform gauze. If one of the ducts is to be drained, it is split and a rubber drainage-tube is inaugurated into the opening with catgut, and is packed about with gauze. [A.B.C.]

5.—Röntgen Ray Therapy.—Ennion G. Williams devotes the most of his article to a description and explanation of the proper mechanism of the röntgen ray apparatus. He states that the treatment of deep growths requires especial attention to the time and distance. The difficulty in reaching them has been the danger of injuring the superficial tissues before the deep growths are affected. Now we know it is not necessary to bring about a necrotic inflammation to destroy a cancer. If we can have the rays penetrate the tissues with modern uniformity we can then hope to destroy the deep growths. The closer the part is to the tube the greater is the difference in the effect upon the skin and the part beneath. We should therefore place the part far off and make due compensation by increasing the duration of exposure directly as the square of the distance, or by referring to the table one can determine the duration for the exposure. His rule is not to expose in 10 days more than the number of minutes required to produce a dermatitis. As this point is approached the exposures are shorter and at longer

intervals in order to watch developments. So soon as the redness is reached and its degree determined, the treatment can be continued and directed according to the indications. [A.B.C.]

6.—Sea-bathing in Skin Diseases.—R. Abraham's experience extends over but 2 summers, but the success attained warrants the suggesting if not recommending this as a reliable curative agent in pityriasis versicolor, herpes tonsurans maculosus et squamosus, chronic eczema, and pruritus senilis. In view of the failure of sea-water to cure when used in bathing establishments the conclusion is that beside the chemie properties of the water, benefit is derived from the longer immersion and the pounding of the billows, thus rubbing the water more thoroughly into the skin, and also from the exposure to the sun in the intervals of the dips which dries the solids of the water into the skin and lastly from the rolling on the sand of the beach which wonderfully helps to remove scales and other pathologic debris, thus affording the water a better chance to penetrate. [H.M.]

7.—Pericarditis.—G. P. Paul writes for the purpose of emphasizing 3 points: (1) The insidious development, and how frequently it is overlooked; (2) that pericarditis of a severe type may develop during the course of a very mild pneumonia; (3) the difficulty of distinguishing obliterative pericarditis from acute general tuberculosis, involving the serous membranes. Very often no subjective symptoms are present at the onset. If during the course of an acute infectious disease the rhythm of the pulse becomes altered, or its rate increases out of proportion to the rise of temperature, or the heart's action becomes tumultuous, or a sudden rise of temperature takes place, a careful examination of the heart should be made. On the other hand, there may be characteristic symptoms. In the majority of cases, however, the diagnosis is made from the physical signs. [H.M.]

8.—Indicators in Gastric Analysis.—A. L. Benedict uses the resorcinsaccharose test for acidity, because more stable than phloroglucinvanillin, and, though less delicate, it will detect 1 part in 4 to 5,000 of diluent. The rose color indicates freeing by heat of HCl in organic combination, or the action of fermentation acids, or both. In titration with an indicator in the capsule with the investigandum dimethylamidoazobenzol is commonly employed, although it gives too high results by about 15 degrees, if we take as the end-reaction the final color change. By reading the free HCl at the point where the bright cherry-red changes to orange and subtracting 15 after the final discharge of color we get more accurate results. The consensus of opinion with regard to titration of chyme is that the estimation of free HCl is approximate, the estimation of total acidity quite exact and that the alizarin and sodium tungstate methods are very inexact, though better than nothing. As a rule 10 cc. should be used as an investigandum to avoid error in readings from too small quantities. Change of tint with the various indicators is a phenomenon of ionization and not a specific combination. Discrepant reports of different observers may be due to differences in visual physiology or possibly histologic variations in the rods and cones. Congo reacts blue with HCl and the mineral acids generally and also with lactic, acetic and butyric acid. Tropeolin 00 changes from magenta to yellow in titrating against a mineral acid with alkali. Lactic acid restores the magenta, but neither acetic nor butyric do so in any reasonable amount. Thus tropeolin is a better indicator for HCl than congo. Its tint, however, is obscured by a brownish cast of the investigandum and the end-point is difficult of detection. [H.M.]

9.—Hydrotherapy, with Special Reference to Psychoses.—R. D. Baker renews the development of hydrotherapy briefly considers its action on the skin as a sense organ, as an excretory organ, and as a heat regulator. He describes a few of the most important hydiatic procedures and their application in some of the infectious fevers. He reports the results in 26 cases of nervous diseases including acute melancholia, acute melancholia with agitation, dementia precox, hysteria, puerperal insanity. The prominent mental symptoms were depression, slowness of thought, little interest in self or surroundings, painful delusions, confusion, hypochondriasis, and insomnia. There was lack of nervous and muscular tone, sluggish circula-

tion, accentuated second sound, no appetite, muddy skin, intestinal fermentation and constipation. In some cases treatment was begun with ablutions at 95° with friction, reducing 5° daily until 65° was reached. When reaction became constant, a sheet bath at 60° was given. A wet pack at 65° was given to some cases followed by a general fan douche at 60° and 25 pounds pressure for 20 seconds, friction, and open-air exercise. In those with flabby, acne-covered skins the wet pack was continued 2 to 3 hours, the colon being irrigated just before with salt solution at 110°. In some cases the douche alone was used. The patients became brighter, more interested, calmer. [H.M.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

Adiposis Physiologica Monstrosa.—A goodly proportion of the attention of the amateur scientist as well as of the average sightseer of Great Britain has recently been directed toward the natural phenomenon now known as "The Fat Boy of Peckham," and denominated by his intimates Johnny Trundley—in the days which preceded the rapid development of his fame and his adipose tissue. And the authority of the Lambeth Police Court has decided that the exhibition of the Peckham prodigy upon the music hall stage is not to be forbidden under the "Act for the Prevention of Cruelty to Children, 1894." Accordingly, this infantile monster of adipose development may rejoice in his 5 years of age, and his 10 stones odd of osteocarnous ponderosity. His income is, for the present, a secure one, so long as his powers of physical endurance can tolerate the exertion of being looked at in public. The only anxiety now expressed by his friends regarding his future is that part of his income should in future be continuously set aside as a provision for a period of future decline of popularity. For the present the physiologic monster can find a Barnum in any civilized country. Every traveling showman knows that excessive obesity has always disputed the prize of public attention with the abnormal extremes of stature. Adiposis is always a reliable competitor with either giantism or dwarfism. What the specific germ may be, whose presence in the blood and tissues determines this lawless proliferation and deposition of adipose matter, does not appear to have hitherto been even guessed at. But its presence is peculiarly free from toxic effects, for any interference with normal physiologic function in such cases as that now under consideration appears to be purely mechanical. As specimens of excessive obesity have always excited curiosity, and it should be added—amusement, reports of such cases have almost necessarily been preserved and made special records in the various ages of recorded history. An interesting writer of the Renaissance period comments on the peculiar custom recorded of the ancient tribe of the *Gordii*, "that whereas other Nations were used to make choice of their Kings for some real excellency or virtue they had in them above others, these people had a custom to advance him to the Throne of their Kingdom, who was the fattest and most corpulent that could be found; perhaps being of a peaceable disposition of themselves, they would have their Princes (whom they could no otherwise restrain) to be clogged at least with fetters of flesh, lest they should prove over active, and more stirring than was conducive to their quiet." The comment appears to be a perfectly judicious one, and tallies well with the Shakespearian judgment delivered some years later—for the perennial instruction of posterity—on the comparative (or contrasted) mental bias of fat and lean men. On the other hand, among the hardy Lacedemonians before Greece sank into the lap of luxury and slavery, the young men were exhibited naked to the *ephoroi* every tenth day. And it "was thought a proof of no ordinary infamy if any one is of unmanly appear-

ance, or if any one appears at all inclined to have a large belly." And in the exercise of their peculiar form of fraternal government, they brought Naucledes, "who was enormously fat in his body, and who had become of a vast size through luxury, into the middle of the assembly; and then, after Lysander had publicly reproached him as an effeminate voluptuary, they nearly banished him from the city, and threatened him that they would certainly do so if he did not reform his life." We are also told by a Greek historian, of Dionysius, a tyrant of Heraclea, who, "by reason of his voluptuous life, and excessive feeding, became so corpulent that by reason of his fat he was pressed with difficulty of breathing, and in a continual fear of suffocation; whereupon his physicians appointed that as oft as he fell into any profound sleep, they should prick his sides and belly with very long and sharp needles; he felt nothing while they passed through the fat, but when they touch'd upon the sensible flesh, then he awaked. . . . He died in the fifty-fifth year of his age; he had reigned thirty-three years, excelling all the Kings his Predecessors for humanity and easiness." This is another item of evidence in favor of the relationship of obesity and benevolence! It also reminds of a case whose record approaches modern times and scientific methods. The celebrated anatomist, Gabriel Fallopius, mentions that "he saw a man, who being extremely fat, his skin was so thickened that he lost all feeling by reason of the over impaction of the Nerves thereby." Donatus, in his "History of Medical Wonders," mentions that "Sanctius, King of Spain, carried such a heap of fat that thence he was called Crassus, being now grown a burden to himself, and left almost nothing untried to be quit of it. At length, by the advice of Garsia, King of Navarre, he made peace with Miramoline, King of Corduba, went over to him, was honorably received, and in his Court was cured by an herb prescribed by the Physicians of that King." Pity it is that history has not preserved the name of that herb! Even the mechanical inconvenience of excessive obesity has proved a source of great gain, as the following case proves: "Anno 1520, there was a Noble Man born in *Diethmarsia*, but living some time in the City of *Stockholm in Sweden*; this man was sent to prison by the command of *Christierne the Second*, King of Denmark; when he came to the prison door, such was his extreme corpulency that they who conducted him were not able to thrust him in at it. The guard that went to convey him thither were to hasten back to assist in the torturing of some other persons; so that being extreme angry at being thus delayed, they thrust him aside into a corner thereabouts, and by this means the man escaped being put into prison as was intended." The corpulency of the good-natured and self-indulgent Pope, Leo X, became so conspicuous in the later years of his life that the phrase "as fat as Pope Leo" remained a household word in Rome for several generations. And England has itself produced in more recent times some noted specimens of colossal corpulency. Edward Bright, of Malden died (in 1750) at the age of 30, weighing 42½ stones. He was an active man till a year or two before his death, when his corpulency so overpowered his strength that his life was a burden." Still we are told that he "left a widow big with her sixth child." But the special historic hero of the Anglo-Saxon adiposity was Daniel Lambert, who was born at Leicester in 1770. He displayed no physical peculiarity till the age of 14. But at 23 he turned the scale at 32 stones; and at the time of his death (in 1809), he weighed 52 stones, being, as might be expected, for some time almost quite helpless.

REVIEW OF LITERATURE

Pathology of Chancre.—S. Ehrman¹ has examined a large number of preputial chancres to determine their anatomy,

especially with relation to bloodvessels and lymph-vessels. He found that the virus after entering, first transuses itself through the interstices of the connective tissue, and at the point of entrance the first changes are noted. Large numbers of newly-formed capillary bloodvessels are seen in the interstices; they accompany, and even precede the virus infiltration. The virus filling these spaces produces induration, and the lymph-vessels arising from these spaces become surrounded by an indurated wall, which contains many of these newly-formed capillary bloodvessels. The subendothelial coat of the lymph-vessels also shows an infiltration which can be discerned, however, only by close examination of the elastic fibers. The virus therefore passes from the tissue spaces into the lumen of the lymph-vessels, producing a reaction in their subendothelial and perivascular tissue with formation of new bloodvessels in both layers; round-cell infiltration is to be noted in both. The perivascular infiltrate produces palpable nodes; they are found at the junction of small with large lymph-vessels, occasionally also along the course of a large one. The nodes contain many small infarcted lymph-vessels; infarcted vessels are also to be found in the subendothelial proliferating zone of the larger lymph-vessels. The nodes surrounding the lymph-vessels soften as the result of regressive metamorphosis of the infiltrate. The capillaries disappear first, cavities form around the lymph-vessels, and the whole is absorbed. It is an involution process through fatty degeneration and not necrobiosis nor cheesy degeneration. [E.L.]

Tortuosity of the Aorta.—J. Sailer and G. E. Pfahler¹ contribute the results of a series of studies upon lesions of the aorta, consisting of clinical, fluoroscopic and radiographic examinations, with autopsy when possible. A source of surprise was the frequency with which some of the lesser signs of aortic aneurysm were present. Among these were inequality of the radial pulses, suprasternal pulsation, tracheal tugging, accentuation of the aortic second sound, and brassy cough. In a number of cases the fluoroscope showed an expansion in the shadow of the aorta at the level of the fifth or sixth dorsal vertebra, extending from a half to 2 inches to the left; it was supposed to be an aneurysmal dilation of the aorta at that point. Of the 18 cases in which this was found, 4 came to autopsy, and no dilation of the aorta was present. On the contrary, the aorta was found to make a bend to the left, not unlike the tortuosity that is frequently observed in cases of atheroma of the peripheral arteries. The writers think it not unlikely that among subjects of arteriosclerosis this tortuosity of the aorta, giving rise to some of the signs of aneurysm of the arch, is relatively a common process. [A.G.E.]

Renal Insufficiency when Intermittent, a Prodrome of Arteriosclerosis.—Landau² gives a formula for determining the insufficiency and suggests variations of from 15 to 30 points daily as enough to indicate the nearness, or prodromal establishment, of arteriosclerosis. However, a renal intermittent insufficiency may have an actual nosologic existence, aside from its symptomatic nature. [T.H.E.]

Relation between Diabetes, Tuberculosis and Arteriosclerosis.—Croner³ believes in an apparent and an actual increase in the number of cases of diabetes; the apparent increase is due to the better instruction of the laity in the symptoms of diabetes, and to the more frequent examinations of the urine for sugar, the actual increase probably to the intermarriage of the Jewish race with the German. He has examined carefully 100 ambulant patients suffering with diabetes, regarding heredity, tuberculosis and arteriosclerosis. In but 9 cases could a clear history of hereditary disposition be made out; 47 of them were tuberculous or had tuberculosis in their families and 32 free of tuberculosis and a tuberculous history had arteriosclerosis. The relationship between tuberculosis and diabetes he explains theoretically either by the absence of a protective substance common to both diseases, or the presence of a substance toxic to both. Tuberculosis usually develops earlier than diabetes and the onset of diabetes may be considered that the individuals have passed beyond the dangers of tuberculosis. The combination with arteriosclerosis is due to disturbances of

nutrition or probably to an irritation of those portions of the cerebrum important to the burning up of sugar; this irritation leads to glycosuria and arteriosclerosis. The amount of sugar is usually small in these cases, and as the cardiac and circulatory symptoms improve it diminishes. Of his patients, 41 were alcoholics, and most of these belonged to a class of people who were more or less under nervous or mental strain. When alcoholism was associated with severe physical labor, diabetes did not usually develop. The tendency to apoplexy of diabetics is explained by their arteriosclerosis. [E.L.]

Visceral Manifestations of the Erythema Group of Skin Diseases.—William Osler¹ adds 11 cases to the 18 that he has previously reported, and considers the features presented by the entire group of 29 cases. There were 11 females, 18 males; 8 were under 10 years, 13 between 10 and 20; 7 cases terminated fatally. Full notes of the last 11 cases are given, followed by a discussion of the nature of the lesions under consideration. In speaking of the diverse etiology of urticaria, Osler says it is not unlikely that the poison, of whatever kind, is of less intrinsic importance than certain transient aspects of cell metabolism. A peculiarity that may be transmitted through several generations, as in angioneurotic edema, must be a morbid susceptibility of tissue or an inherited peculiarity of metabolism, or both. The visceral complications of the erythemas form 2 great groups—the angioneurotic and the inflammatory. These are considered according to the organ attacked. In 2 cases there were brain symptoms; 3 had edema of the glottis, 3 pneumonia; 25 had gastrointestinal symptoms, the most prominent being recurring attacks of colic; in 14 there was acute nephritis; arthritis or arthritic pains occurred in 17 cases, but the joint lesions were slight; hemorrhages were present in a number of cases. The chief danger in these cases is from the kidneys, and early precautions should be taken to recognize the nephritis and prevent its progress, protracted rest in bed and a milk diet being the best means at our disposal. [A.G.E.]

Experimental Investigations Concerning Icterus.—The experiments of G. Joannovic² were made on dogs, by poisoning with toluyldiamin, by injecting hemolytic serum, and by ligating and cutting the ductus choledochus. Two forms of icterus may be distinguished—the hemolytic icterus, and the stagnation jaundice. The latter is slower in developing and never reaches the high degree attained by the hemolytic jaundice. The stagnation of bile after obstruction of the ductus choledochus occurs first in the large biliary passages and the interacinous ducts. In hemolytic icterus the stagnation is principally intrahepatic. In the icterus of obstruction there is no splenic tumor, while it is invariably present in the hemolytic form. The splenic tumor is spodogenic, *i. e.*, due to the debris of the destroyed red corpuscles. The function of the spleen favors in such cases the development of the icterus, as it actively participates in the destruction of injured corpuscles. [B.K.]

Relation between Influenza and Appendicitis.—Schultes³ has had occasion to watch 4 epidemics of influenza; during 3 of them no cases of appendicitis were observed, but the last epidemic, consisting of 156 cases, was characterized by many appendiceal complications. In 3 of them the influenza bacillus could be considered the causal factor of the abdominal infection. All 3 recovered without operation. [E.L.]

The Source of Infection in Tuberculosis.—S. Davies⁴ bases his paper on an examination into 50 deaths of children under 10, certified to be from tuberculosis or meningitis, and 178 notified cases in adults. Of the former there were 34 cases of general and meningeal tuberculosis. In 17 of these there was a clear history of contact with a declared case of pulmonary tuberculosis, in 7 with a doubtful case, in 4 probable contact. In one there was contact with a case of lupus. Among the adults the questions of workshop and public-house infections were especially investigated. The workshop is regarded as offering opportunity for infection, but not as being in itself an important source of infection, *i. e.*, through infected dust, etc.

The public-house is shown to be a much more important source of infection than is the workshop. Infected spray from coughing is probably as much at fault as dust from the floor. Samples of sweepings from the floors of 6 public-house bars and a like number of arsenal workshops showed the presence of tubercle bacilli in 2 of the former and none of the latter. J. Niven,¹ in an article on the influence of occupation on the production of tuberculosis, comes to substantially the same conclusion regarding public-house infection. Two factors which cause men to have a much higher deathrate than women are spitting in the workroom and drinking in public-houses. The aggregate effect of these 2 factors is greater than that of particular occupational causes. [A.G.E.]

Cause and Treatment of Chronic Rheumatism.—Ralph Stockman² states that acute rheumatism may cause fibrous thickening of the valves of the heart, fibrous induration of the aponeurosis, fascias, ligaments, nerve-sheaths, etc., but these are the lesions of the original disease and not an indefinite continuation of it. Such indurations of the fibrous tissue give rise to bands referred to the muscles, joints and nerves, but these symptoms and the lesion causing them cannot properly be regarded as the chronic stage of acute rheumatism, especially as acute rheumatism is not the only condition which causes them. However, the name chronic rheumatism has been so long applied to this chronic and painful condition of the muscles and joints, that it is now retained as a matter of convenience. It is now recognized that the articular structures proper, that is the cartilage, synovial membrane and bones, are not primarily affected in chronic rheumatism, but that the parts implicated are the fibrous ligaments of the joints and more especially the fibrous tissues of the muscles and bones. He enters at length upon the pathology. Not only may acute rheumatism result in sequels, as above enumerated, but also true influenza may cause the condition often spoken of as chronic rheumatism; sore throat is also another predisposing factor; likewise local injuries to joints and muscles have the same effect; in many cases no cause can be assigned. In reference, the only means which he has found of special and definite value are massage and exercise, the faradic current, and the injection of solutions of chromic acid into any of the fibrous indurations which are sufficiently large and well defined to permit of its being done. Of the 3, massage is much more efficacious. General massage will not do, but it must be specially directed to any nodules or thickening which can be felt. In comparatively recent cases these nodules soon subside, but in the more chronic ones a prolonged treatment of a year or more is often necessary. [A.B.C.]

Salipyrin Eruption.—Dittmar³ observed in a woman of 28, whom he gave 1 gm. (15 gr.) of salipyrin for headache, an eruption which began to show itself a quarter of an hour after partaking of the drug. It consisted of hives, varying in size from a pinhead to several inches, and appearing on all parts of the body, excepting the head, neck, hands, and feet. The itching was intolerable. After an hour the hives began to flatten and had disappeared after 4 hours. The condition was associated with nausea, depression, rapid, small pulse; no symptoms on the part of the auditory apparatus as cyanosis. The author sees in this eruption the effect of antipyrin, which is followed by all sorts of exanthemas. The absence of auditory symptoms speak against it being due to the salicylic acid component. [E.L.]

Diastasis of the Recti Muscles in Rickets.—A. P. Francine⁴ reports a conspicuous example of this condition occurring in a colored male child of 15 months. The diastasis is the width of 3 fingers, has existed since the age of 5 months, and shows a slight tendency to increase, the writer finds no mention of this condition in the literature of rickets, although he has found it present in 7 of 10 patients, varying in age from 6 months to 9 years. The condition is due to developmental lack of tonicity of the muscular system, and is induced secondarily by the associated tympanites of gastrointestinal fermentation. It is improbable that such muscles ever regain their lost

⁴ Archives of Pediatrics, February, 1904.

tonicity, and early diastasis may be in some instances a predisposing factor toward visceral ptoses. [A.G.E.]

Acute Leukemia.—M. Leclerc¹ relates a case of acute leukemia, in which the leukocytosis consisted of 96% lymphocytes, principally small ones, and only 4% polymorphonuclears, with no large mononuclears or eosinophiles. He considers the clinical picture of acute leukemia to be as follows: An anemia of sudden onset with rapid course, accompanied by fever. The increase in leukocytes is almost always a lymphocytosis, and there are marked alterations in the red corpuscles. Hemorrhages are frequent. There may be hypertrophy of the spleen and lymphatic glands; but this may be very slight, or even absent. A new symptom, described by Hayem, is nonretractibility of the clot. [R.K.]

Extrasystolic Intermittent Pulse.—D. Gerhardt² reports the case of a man who, recovering from acute articular rheumatism, had a markedly intermittent pulse, dropping a beat every third to fourth pulse. This only lasted a few days. Graphic tracings of arterial and venous pulse showed that this was not due, as is usually the case, to extrasystolic contractions, but rather to extrasystolic. The contractions of the auricle were noticed, but not the contractions of the ventricle. It is evident that the ventricular irritability was either diminished or there was a disturbance of the conductivity of the impulse between auricle and ventricle. Why this transient failure of the ventricular contraction should occur in apparently normal heart is something the author cannot explain. [E.L.]

The Physical Signs of Lobar Pneumonia.—L. A. Conner and G. E. Dodge³ present a valuable contribution to this subject, the records of 392 cases forming the basis of the paper. They place the physical signs of a beginning pneumonia in the following order of relative frequency and importance: 1. A circumscribed area of feeble, indistinct breathing as compared with the breathing at a corresponding point on the opposite side (with the patient, if possible, in a sitting position). 2. A circumscribed area of impaired resonance, with or without a tympanic quality, obtained under similar precautions. 3. The crepitant rale. 4. A slight increase in the intensity and clearness of the vocal resonance. The signs of the second stage are bronchial breathing and bronchophony. In 4 cases of undoubted pneumonia, neither could be found at any time during the course of the disease. The relation of the disappearance of bronchial breathing to defervescence is briefly considered, the disappearance occurring before defervescence in 20% of the cases, the majority of the remainder occurring with, or from 1 to 7 days after, defervescence, 10% taking place more than 7 days after. The writers consider it entirely unwarranted to apply the name of central pneumonia to all cases in which the signs of consolidation are late in appearing. The usual condition in these cases is not that of a centrally situated consolidation slowly working its way to the surface, but rather one of very slow progress from engorgement to complete hepatization. [A.G.E.]

Levulose.—Fuerst⁴ thinks that levulose has many advantages for pediatric use being especially suited for dietetic purposes; it is extremely valuable in chemic disturbances of nutrition. Ordinary cane sugar is very apt to cause dyspepsia or intestinal fermentation in nurslings and in powder form is very apt to be adulterated. Milk sugar is not sweet enough in small amounts; in large amounts it causes diarrhea, nor can its purity be relied on. Levulose is a carbohydrate that has most important advantages as a sweetener of infants' food. Its molecular form and caloric value is similar to that of milk sugar and the agreeable taste that it gives to milk renders it most suitable. It never causes gastric or intestinal disturbance and is very rapidly assimilated. He employed it in 17 cases with different diseases; the dietetic and hygienic conditions were as far as possible regulated and in all of them several weeks of levulose caused visible improvement and increases in weight. He divides the cases in which he used the remedy into 3 classes: 1. Infants fed chiefly on cow's milk and suffering

from malnutrition. 2. Children over 2 years old suffering from insufficient nutrition. 3. Sick or convalescent children. Through its ready assimilation levulose combats tuberculous infections of the mesenteric glands and in combination with an appropriate diet in children predisposed to tuberculosis it will assist in preventing the disease. Levulose increases carbonic acid production, promotes absorption and assimilation and causes the deposition of fat in the tissues and the improved nutrition enhances the powers of resistance in the infantile organism. [E.L.]

The Source of Scarlatinal Infection.—R. E. Lauder¹ Medical Superintendent of the Bureau and Port Fever Hospital, Southampton, announces his belief that the contagion of scarlet fever is not carried by the desquamating epithelium of the patient, but is conveyed by the mucus and other secretions from the mouth and upper respiratory passages. In confirmation of this view, during the year 1903 he tabulated the 325 patients which came under his care and compared them with those treated during the previous year. Those treated during the year 1903 are divided into 3 groups, the first was limited to 33, which were dismissed after 33 days' residence in the hospital, without peeling or complication and there were no return cases, that is, cases whose infection was attributed to the dismissed cases. The second group of 204 patients was dismissed after 28 days in the hospital and there were peeling and desquamation without other complications. From these there were 2 return cases. The third group comprised 88 cases with an average detention of 50 days in the hospital. These had various complications of the upper respiratory tract, and from them were 5 return cases. During 1902 the average period of detention in the hospital was 48 days with 4.27% of return cases; while in 1903 the average period of detention was 34 days with 2.15% return cases. The fewer return cases in 1903 is attributed to the segregation and longer detention of those cases with complications of nose, throat and upper respiratory passages. [A.B.C.]

Paroxysmal Hemoglobinuria Produced by Cold.—J. Donath² reports 3 cases of hemoglobinuria, in which the paroxysms were brought on by exposure to cold weather. Two other previously reported cases are also referred to. There was a previous history of syphilis in 3 of the 5 cases. All showed at times the typical paroxysms, characterized by premonitory symptoms, chill, fever and sweating. The first paroxysm was usually preceded by lumbar pain. One case exhibited vasomotor disturbances of the skin, which pointed to a possible vasomotor origin of the hemoglobinuria. The regeneration of the blood in all cases was very rapid, after the paroxysms passed, and was accompanied by the appearance of numerous nucleated red corpuscles. No trace of blood pigment could be found in the blood serum between the attacks, but hemoglobinemia was constant during the paroxysms. Experiments made by the author show that the blood disintegration was neither due to the direct influence of cold on the red corpuscles, nor to a pure mechanical injury of them, but upon the hemolytic influence of the blood-plasma. [B.K.]

Excretory Powers of the Diseased Kidneys.—L. Mohr³ has studied the excretion of several substances after their administration in cases of nephritis. The substances administered were Liebig's extract of beef, sodium phosphate, urea, and sodium chlorid. The urine showed a variable excretion of water, nitrogen, and salts, with a good excretion of ammonia and purin bases. Increased administration of urea did not increase its elimination. Increase in the administrations of purins and extractives was promptly followed by increased excretion of these substances. The phosphoric acid excretion was irregular. Administration of sodium chlorid was followed by an increase in its excretion far exceeding the amount given, thus showing that the previously retained salt is washed out by this means. The only exception was found in a case of acute nephritis with edema. The experiments also show that the excretion of salt and of water are independent of each other. [B.K.]

GENERAL SURGERY

A. B. CRAIG MARTIN B. TINKER C. A. ORR

EDITORIAL COMMENT

Luxation of any of the articulations of the vertebral column is well known, except, of course, by the osteopaths, to constitute one of the most serious of all surgical lesions. Fortunately, it is also, except in osteopathic practice, one of the most rare. Indeed, on account of the anatomic arrangement of the articular processes in the lumbar region, and of both articular and spinous processes in the less movable dorsal segment, the occurrence of vertebral luxation in either of these regions, without the coexistence of fracture, amounts to a physical impossibility. The danger ensuing upon vertebral luxation is, very obviously, due to the simultaneous lesion of the contained spinal cord, which, in the great majority of instances, is crushed. It is only in the cervical region that a remote possibility exists of the occurrence of luxation without coexisting fracture. And the most frequent seat of cervical luxation is at the articulations of the sixth cervical vertebra. In his thesis on this subject (published in 1851), Richet collected 11 cases; the luxation between the sixth and seventh vertebrae is, however, a little more frequent than that between the fifth and sixth. M. M. Patel and Viannay¹ have recently published clinical records of two cases of cervical luxation.

One was of a bilateral, forward luxation of the fifth vertebra, of six years' standing; the second was of a unilateral forward luxation of the third vertebra, dating from two months. The former case was first seen by these physicians four years after the original accident. The patient was an agricultural laborer, aged 64. He had been sleeping on the landing of a staircase which had no balustrade, from which he fell to the floor below—a distance of 4.5 meters. The history did not say how, probably on his head. He was found in a state of coma, which lasted two hours; on recovery he was unable to move the right arm or leg. He was treated in hospital, and the limbs recovered voluntary movement—but to an imperfect degree. He continued to be easily fatigued, and prolonged exertion brought about severe pain along the spine. By degrees, however, the symptoms disappeared, and he was able to resume his ordinary labors, but his right foot still dragged somewhat, and he readily tripped and fell when walking in the dark on uneven ground. When examined by MM. Patel and Viannay, a prominence of the sixth cervical process was found to exist, with a depression above. The movements of the head were very limited—except that of rotation. Pharyngeal examination revealed nothing. The reflexes were exaggerated, especially on the right side. There was diminished sensibility of the cutaneous surface over the left half of the body, the face excepted. He had suffered from constipation and abdominal tympanites ever since the accident. The second case was that of a young man of 22, who had been adjusting the traces of a plough to which a pair of oxen were yoked; when they suddenly started off, and dragged him for a distance of about 100 meters. He lost consciousness, but did not know for how long. On recovering, he was able to sit upright, but found his neck painful and stiff. He was able to walk to his home, a distance of 150 meters. The neck and shoulders continued to be very painful, and he was unable to raise his arms, although he could use his hands. His state, however, gradually improved. On examination at hospital, the head and upper part of the neck were found slightly flexed; with a slight lateral inclination, and a little fixed rotation to the left, the neck appeared sunken toward the shoulders; there was dorsal scoliosis, with the convexity to the right. The patient remarked that his chin rested too near the thorax. There was a painful point in the position of the third cervical spinous process. Pharyngeal examination showed a vertebral prominence at the level of the soft palate. It was then almost two months after the accident, and the scapular muscles, with the deltoid and biceps of each side, displayed atrophy and loss of power. The scapulas were "winged." The triceps presented no change on either side. Traction, combined with lateral and anteroposterior movements of the neck—without anesthesia—diminished the deformity, and appeared to improve the condition of the upper limbs. But he returned, after the lapse of a month, with increased and progressing trouble, which had extended to the muscles of the lower limbs, and was complicated with constipation and retention of urine. Continuous extension was then applied to the cervical spine, upon which the patient rapidly improved, and at the end of another month was reported convalescent.

In this class of injuries, thanks to the wider lumen of the spinal canal, luxation may occur without considerable lesion of the contained cord, which is hardly possible in the dorsal region. In these two cases it is especially interesting to note that the bilateral luxation produced unilateral nerve lesions; while the unilateral one presented bilateral nerve complications—of a much more pronounced type. As the first case was of so long standing, its interest was chiefly pathologic, as no definite radical treatment could be thought of.

REVIEW OF LITERATURE

Treatment of Inguinal Hernia by Exercise.—Jay W. Seaver¹ presents a further report on the success of a treatment of inguinal hernia in the young as outlined in the same journal in 1900. This consists of voluntary movements of the abdominal muscles that can soon be mastered if the patient is deeply in earnest in the matter. A description of 10 exercises of special character that are to be employed 2 or 3 times a day for periods of 5 to 8 minutes each is given. In addition, the patient is allowed to indulge in almost any form of athletic or gymnastic work, thus greatly enlarging the list of movements. From an experience reaching over a sufficient length of time to test the permanent value of the cures effected, Seaver is convinced that the exercise treatment offers a means of relief in more than 75% of patients under 25. It is not applicable to some cases, because of their mental attitude toward exercise, and to a few others because of peculiar anatomic conditions. In occasional cases success has followed systematic exercise in persons who have reached physical maturity. In one instance cited, the patient was a man of 38, who had worn a truss for 12 years. With the treatment of inguinal hernia by exercise, Seaver especially emphasizes the necessity of using a flat pad that will not open the inguinal ring by the pressure of a convexity into it from without, as is the case with many of the truss pads worn. He employs a disc of hard polished wood or rubber 60 mm. (2½ in.) in diameter, with a segment removed from the side that lies against Poupart's ligament, this obviating the tendency of movements of the thigh to displace the pad from the abdominal wall. [A.G.E.]

Substitution of the Radial Diaphysis by an Ivory Rod.—K. Vogel² reports the case of a girl of 8, whose radius underwent caries from epiphysis to epiphysis. The entire diaphysis came away as one sequestrum. After a time, as the forearm was beginning to lean toward the radial side, an ivory rod was fitted into the epiphysis at each end, with perfect, ultimate success. The child uses its arm as well as other children do, only pronation and supination being somewhat limited. Skiagraphic pictures show the condition before the ivory rod was put in place, immediately afterward, and one year later. The last picture shows considerable proliferation from the retained periosteum and the epiphysis. [E.L.]

The Operative Treatment of Diffuse Purulent Peritonitis.—M. M. Mirsnoff³ believes that operation is useless in general puerperal or postoperative peritonitis due to streptococci or to staphylococci. Operation may retard the fatal issue in such cases, but is powerless to avert it. On the other hand, when the peritonitis runs a protracted course, being caused by the coli bacillus or the gonococcus, or even by enfeebled cultures of pus cocci, then a timely evacuation of the peritoneal cavity and the removal of the infectious source is decidedly beneficial. In these instances it is advisable to pack the Douglasian cavities and other folds with gauze, instead of using free flushing and glass or rubber drainage-tubes. [L.J.]

Surgical Treatment of Perigastric Adhesions.—Percy Paton⁴ states that operative experience has proved conclusively that certain perigastric adhesions are, in many instances, the cause of prolonged gastric disturbances. It has been shown by postmortem records that in 5% of examinations evidence of an active ulcer of the stomach or the scar of an old one is present. Fenwick believes that 40% of such ulcers cause adhesions. The

¹ Yale Medical Journal, February, 1904.² Deutsche medizinische Wochenschrift, November 12, 1903, Vol. xxix, No. 46.³ Journal Akousherstwa, November, 1903.⁴ The Lancet, February 6, 1904.¹ Gazette des Hôpitaux, August 6, 1903.

following causes may be assigned for perigastric adhesions in addition to ulcers of the stomach: Gallstones, traumatism, malignant disease, pancreatic disease, umbilical hernia, tubercle and syphilis. In 123 cases with adhesions Fenwick found that the adhesions were to the pancreas or liver, or both, in 92 instances, and in the remaining 31 cases the stomach was attached to the colon, the liver, spleen or more than one of these organs. He holds that, in those instances in which gastric disturbance has existed for a considerable length of time and will not yield to medical treatment, we are entirely warranted in advising surgical interference for the relief of the patients. In support of this he recites the histories of 42 cases which have been operated upon by various surgeons, 4 of which were the author's own. [A.B.C.]

Narcosis by the Scopolamin-morphin Method.—Max Stolz¹ concluded that this method possessed many disadvantages, and is unreliable and dangerous. Of 465 patients so treated, only 309 became anesthetic, the remainder requiring inhalation narcosis. Of this number, three died as a result of the injection. One was profoundly, and 9 slightly asphyxiated, and heart weakness was frequently observed. [J.H.W.R.]

Surgery of Cerebral Tumors.—George Woolsey² contributes a clinical and statistical study of cerebral tumors operated upon during the past 5 years. He has been able to collect 101 cases, of which he has had 5-3 tumors and 2 cysts. The principal object of the study was to determine if recent advances in localization and technic justify the extension of the indications for operation as given by the more conservative surgeons, many of whom are believed by Woolsey to be ultra-conservative. He takes a more hopeful view of the surgery of cerebral tumors. Some of his conclusions are: (1) The sphere of operation for cerebral tumors may be and has been extended to the prefrontal, parietal, and occipital regions, in addition to the motor area; (2) the prognosis is as good or even better than in operations for malignant growths elsewhere; (3) palliative operation is strongly indicated to relieve symptoms where localization cannot be accurately made or the tumor cannot be removed. Exploratory operation is contraindicated; (4) the osteoplastic method should be employed and the most rapid and perfect technic allowed by the circumstances, should be adopted. For opening the skull, Woolsey has employed in his last 2 cases Doyen's electric circular saw, with much satisfaction. He believes that hemorrhage is the chief cause of shock in the surgery of cerebral tumors. [A.G.E.]

Hygroma of Bursa beneath the Serratus Magnus Muscle.—The existence of the subscapular bursa is known to be rare. Reports of inflammation, there, are exceptional. Gruber has studied one in which he found the bursa to be $\frac{1}{2}$ in. to 1 in. in diameter in normal state. Giuseppe Betagh³ reports an hygroma, occurring on the right side beneath the scapula in a laborer of 33, the tumefaction being as large as an orange. The mass was removed and found to contain a cavity with about 4.5 cc. (15 oz.), liquid, slightly sanguinous, alkaline in reaction. Other cases are appended. The diagnosis would be very difficult in the absence of exploratory puncture. The etiology is not clear. [T.H.E.]

The Prevention of Peritoneal Adhesions.—Percy Paton⁴ quotes approvingly the opinion of Carl Vogel on the formation and prevention of interperitoneal adhesions. After the trial of a large number of different substances to prevent agglutination of peritoneal surfaces which were likely to adhere, Vogel came to the conclusion that none of them was of much avail and that of those tried, the best results were obtained with either sterile saline solution introduced in quantity into the abdomen or a small quantity of sterile solution composed of gum arabic, 1 part, saline solution, 2 parts. He found of much more importance in the prevention of adhesions and readhesions was the promotion of movement among the viscera, while allowing the patient to move from side to side more than is usual after abdominal section, and by employing gentle massage to the abdomen, and particularly by promoting peristalsis. For the latter purpose he found that a mild laxative and the use of

atropin, physostigma, and the salicylates were of valuable aid. Paton believes that the old treatment of keeping cases of abdominal section too rigidly at rest with the bowels confined should give way to the better plan of opening the bowel at a very early date, except in extreme and rare cases where it is contraindicated. [A.B.C.]

A Case of Evisceration.—W. E. Ground¹ reports the case of a man who was gored by a bull, the entire abdominal wall being torn through from the external abdominal ring to the tenth rib. The man crawled to his house, a distance of 200 feet, where he lay for 2 hours with nearly all of the small intestine out in his clothing. Operation was then performed, the man reacted promptly, no infection occurred, and recovery followed without an untoward symptom of any kind. Ground reports the case to emphasize his dissension from the views of some surgeons regarding the nature of infection. He rejects the statement that infection is a question of dose instead of virulence of organisms; the experience from 800 abdominal operations and from his capacity as railway surgeon leads him to believe that the number of germs has little to do with determining infection, this being due almost absolutely to the inherent virulence of the bacteria. The study of wound-healing away from aggregations of people in enclosures, away from direct communication with septic cases (the case reported, for instance), shows almost universal healing of extensive wounds by primary union without particular pains to produce asepsis. The practical point emphasized is that surgeons should never touch a septic case nor examine a rectum or vagina without wearing gloves. [A.G.E.]

Treatment of Inguinal Bubo.—Bockenheimer² treats buboes arising in the course of gonorrhea or soft chancre by puncturing the skin above the gland before it inflames, and withdrawing the pus with the syringe. He then injects from 2 cc. to 3 cc. of a solution of hydrarg. benz. 2 gm. ($\frac{1}{2}$ dram) natrii chlorati 2 gm. ($\frac{1}{2}$ dram) and aqu. destill. ad 200 gm. (7 ounces). If the puncture is not made until the skin is inflamed a fistula is likely to form. The puncture should be made into the upper part of the bubo to prevent the injected fluid from running off. From 2 to 3 injections at intervals of a week will usually cure the condition. [E.L.]

Postoperative Hematemesis.—W. J. S. McKay³ gives brief note on 7 cases of this complication, 3 of the cases in which it occurred being fatal. He suggests that the chief cause of hematemesis after laparotomy is shock which acts by causing portal congestion. The many cases reported by different surgeons include all the various abdominal operations; some of the patients were septic, some were not; some had local anesthesia, some general; the only feature common to all is shock. This condition causes an over-filling of the abdominal veins and this in turn a dilation of the coarse capillary network surrounding the mouths of the gastric glands; from these capillaries hemorrhage occurs. In some cases shock and portal congestion may not be sufficient to account for the hematemesis and we may suppose that predisposing conditions, as ulceration or abrasion, are present. As a part of the treatment of hematemesis, McKay recommends the administration of suprarenal capsule with chlorotone or 10 minim doses of adrenalin every hour for 3 hours. Operative interference is considered to be quite out of place. [A.G.E.]

Intestinal Anastomosis by McGraw's Elastic Ligature.—W. T. Henderson⁴ reports that a man of 31 suffered from strangulated inguinal hernia. The author was called late in the case; herniotomy was performed and the bowel was found gangrenous; temporary relief was afforded by a large fecal fistula which showed no tendency to heal. Five weeks after the primary operation laparotomy was performed, and the fistula being in a loop of the small intestine but a short distance from the ileocecal valve, the ileum above the valve was attached to the ascending colon by means of McGraw's elastic ligature, the bite of bowel and colon within the elastic ligature being 12 inches long; the ileocecal valve was thus entirely sidetracked. The patient made an uneventful recovery with primary union

in the abdominal wound, and the fistula closed within a short time. The author is an advocate of this means of effecting anastomosis in cases in which it is indicated—that is, in those instances in which an immediate anastomosis is not urgent—[A.B.C.]

The Operative Treatment of Prostatic Hypertrophy.—B. N. Kholzow¹ makes a comparative estimate of the various current operations. He considers vasectomy indicated in the first and second stages of prostatic hypertrophy, when the disturbances of micturition cannot be otherwise palliated, when catheterization is difficult, when there is acute retention of urine. In these cases the simplest and least dangerous operation is to be preferred and vasectomy fulfils these conditions. With the subsequent reduced hyperemia the manifold disturbances will often pass away. Should this hope not be realized, we may perform a secondary Bottini operation or a prostatectomy. Perineal prostatectomy is called for in the third stage of hypertrophy, if the general health is good and the urinary tract not much damaged. Suprapubic prostatectomy is indicated in partial hypertrophy of the prostate, the enlarged portion projecting like a tumor on a pedicle into the bladder. Bottini's method is called for in the same cases as perineal prostatectomy, when the patient is very old, the general health poor and the urinary tract considerably damaged. [L.J.]

Treatment of Cancer of the Breast by Operation.—W. Watson Cheyne² states that on the average about 50% of all patients operated upon for cancer of the breast will remain well for a number of years, and in those cases in which the tumor is small, and glandular affection slight, the proportion of successes will be considerably greater. Recurrence takes place most frequently internally, and causes less suffering than if operation had not been performed. In the modern operation recurrence is rendered less probable by the fact that cancerous deposits are not cut into at the time of operation and the cells thereby distributed through the tissues. At its beginning, cancer is a local disease and amenable to surgical treatment, hence the importance of early operation. The cancer cells are the direct progeny of the cells in the original tumor, and epithelial growths cannot originate in lymphatic glands or nonepithelial structures. He believes in the existence of a general tendency to cancerous development, but even if this is the case and the patient may, at a later period, develop another cancer, it is no argument against removal of the disease as completely as possible in its present situation. Above all things we should remember that the patient's only chance lies in the *first* operation, and this must be thorough, however limited the disease. [A.B.C.]

TREATMENT

SOLOMON SOLIS COHEN

L. F. APPLEMAN

E. LINDAUER

REVIEW OF LITERATURE

Preservation of Bactericidal Properties of Milk.—E. v. Behring³ has found that a solution of formalin, 1 to 4,000, will preserve fresh milk for 8 days, at the end of which time it cannot be told from new milk; solutions of this strength cannot be detected by the most sensitive palate. If a 1 to 10,000 is added to the milk, it will not sour for 8 days. Formalin will also preserve the immune bodies which are present in the milk of cows treated by Behring's method. Ordinarily, after standing, these bodies have disappeared, but according to our present tests they are just as plentiful in formalized milk after a week as when first put in the jar. Fresh milk possesses certain bactericidal properties, which are destroyed by boiling; the formalin solution increases this bactericidal property. To reduce infant mortality, Behring therefore advises fresh milk, uncooked, for infants, or if it has to be transported, to add formalin to it. [E.L.]

Walking and Running as Therapeutic Exercises.—L. H. Gulick⁴ shows that the effects of walking vary according to speed, duration, and the character of the ground passed over.

When the walk is not too rapid for the natural swing of the leg to bring the foot forward at the completion of each step, it is a very moderate exercise. The support of the pelvis upon the 2 legs in alternation is an entirely automatic process; cardiac activity is somewhat, but not greatly, accelerated, and the respiration is quickened in proportion to the energy expended. The objection commonly raised against walking as a general exercise is that the arms are not used, and that the muscles of the trunk receive no exercise. During rapid walking, on the other hand, the arms are used continuously; at each stride the pelvis is slightly rotated in order to lengthen the stride; the psoas magnus and the long head of the rectus femoris are called into active operation in pulling the thigh forward, while the action of the same muscles is needed to pull the leg forward, particularly at the end of the step. Exercise of all the muscles of the body is not indispensable, the important element is the exercise of large groups of muscles. This is accomplished, to a large extent, by walking—particularly by walking as rapidly as 4 miles in the hour. When much exercise at this rate seems inadvisable, the same result can be attained by interrupting the walk with frequent rests. The agitation of the body at every step tends directly to stimulate the functions of all the abdominal organs. In this respect walking far excels cycling, in which the body is relatively motionless, being supported on the tuberosities of the ischium. When the patient can utilize the advantages of a hill, walking can be made even more effective than on the level. There is no better or quicker way of modifying the great organic functions of respiration, circulation and digestion than by walking up a grade. This should be done with frequent rests to prevent embarrassment of the cardiac or pulmonary systems; but it is important that the exercise be sufficient to call for steady, conscious effort. The effects of running differ from those of walking somewhat in kind, but even more in degree. In running at any ordinary rate of speed the leg does not have to be pulled forward at each stride; and, on the other hand, the up-and-down motion of the body is greater in running than in walking; thus, the effect upon the abdominal organs is greater, the energy expended is greater, and the effect upon the general system is more marked. The increased activity of the diaphragm also stimulates the circulation of blood in the abdominal organs. Running should not be pursued to the point of circulatory or respiratory embarrassment, not only because of the effect upon these organs themselves, but because at this point great effort of the will is necessary to force the individual to continue; it is thus neurally exhausting. The maximum of general effect is secured by a series of short runs with complete rest between, rather than by walking slowly for a long distance. Rapid running so quickly exhausts the organism as to be but little suited for general exercise. Alternate slow running and walking meet so many of the conditions of general exercise, both negative and positive, that Gulick is confident it will have a large place in the future as it has had in the past in general exercise. It is not of prime necessity that the muscles of the arms be greatly exercised. Slow walking with running brings into play the general activities of the body in an excellent way. In gymnasiums having no running track it is possible to have a large number running on the gymnasium floor by means of what is called "maze running."

Hydriatic Treatment of Pulmonary Tuberculosis.—B. Buxbaum¹ recommends that tuberculous individuals immediately after leaving bed in the morning should be given cold rubs or baths to a part of their body with water at 50° F. to 55° F. Patients with fever, confined to their beds, should have moist bandages applied to chest and back, and these bandages covered with dry ones. During the forenoon cold applications should be made to the heart for $\frac{1}{2}$ to 1 hour. Patients not confined to bed should lie down for a part of every morning for the purpose of cold water treatment to the heart. This should be repeated in the afternoon, and followed by a 15-minute douche of water of the same temperature as that used early in the day. Before going to bed the morning ablution is repeated and followed by application of cold bandages to chest and back. [E.L.] [There must be individualization in hydrotherapy as

¹ Russki Vrach, January 24, 1904.

² The Lancet, March 12, 1904.

³ Therapie der Gegenwart, 1904, Vol. xlv, No. 1.

⁴ System of Physiologic Therapeutics, Vol. vii.

¹ Allgemeine Wiener medicinische Wochenschrift, 1903, xlviii, 547.

well as in drug therapy. This method, useful for many, is harmful for some. S.S.C.]

Serum Treatment of Hay-fever.—L. S. Somers¹ reports the use of serum in 10 cases, all of them well developed when first seen. The serum was from animals inoculated with the pollen toxin of golden rod, both the liquid serum and the powder prepared from it being used. With the exception of 1 case, the results were most gratifying. While the application of antitoxin to the nose relieves hay-asthma, it apparently has no effect upon an accompanying bronchitis or semiasthmatic condition not dependent upon the hay-fever. The general conclusions reached are that the golden rod antitoxin produces prompt and positive amelioration of the symptoms of fall hay-fever in the majority of cases. [A.G.E.]

Felix Mas and Optic Nerve.—In 2 cases of ankylostomiasis, Habercamp² prescribed the ethereal extract of felix mas in capsules, giving 1 patient 10 gm. (2½ dr.), another 8 gm. (2 dr.) on 3 different days; this in each instance was followed by calomel. One of the patients became completely blind after the third dose; in the other, the visual power diminished to counting of fingers at several meters. The initial clouding of the optic disc and venous stasis were replaced at an early date by the typical picture of optic atrophy with narrowing of the bloodvessels. Habercamp believes the blindness to have been due to acute degeneration of the nerve-fibers, and not as has been suggested by others, to disease of the retinal vessels. The amount of the drug has no bearing on the production of the intoxication, as 46 gm. (1½ oz.) have been taken without injury. Calomel was given instead of castor-oil, because as is well known, filicic acid, the active principle of aspidium root, is easier dissolved in oils and absorbed. [E.L.]

Manual Correction of Club-foot.—H. A. Wilson³ believes that corrective manipulations skilfully applied and persistently resorted to will give far better ultimate usefulness of the foot than any other corrective measure. The dangers lie, however, in modifying the shape of the still very soft bones of the tarsus by the use of undue force. The cicatrices made by tenotomies may often be avoided, as well as the more or less extensive muscular atrophy that is associated with the use of many forms of braces. After the application of the force a few times by himself, the operator may usually instruct the mother in such a way that she can readily apply this force from time to time during the day, very much to the advantage of the child. It is of primary importance that in making corrective applications to the feet, the knee of the leg operated upon should be flexed to very nearly a right angle to prevent rotation of the hip instead of correction at the tarsus. The child is seated upon the mother's lap with the knee bent. The operator is seated directly opposite. Assuming that the left foot has equinovarus, the operator places his right thumb above the external malleolus, while his fingers grasp the internal aspect of the os calcis and during the process of subsequent manipulations are enabled to overcome the varus condition of the heel. His left hand is used in such a manner as to keep the toes and metatarsal bones all in their parallel relationship to each other. His thumb placed on the dorsum of the foot still further aids in maintaining the correct relationship of these long bones of the foot. With his hands in the position described he is enabled to overcorrect the foot as to its varus, and also by changing the direction of motion to overcome its equinus. If the equinus is of more marked degree, it may be necessary for him to change the position of his hands, so that his left hand will firmly grasp the leg just below the bent knee. His right hand with the fingers under the plantar surface of the foot is used to bring the foot into a position of dorsal flexion, in which he is materially aided by his right thumb placed over the dorsal aspect of the astragalotibial articulation. Wilson, likewise, cautions against certain erroneous procedures which cause pain and accomplish no good result.

Prevention of Iodism.—F. Lesser⁴ says that iodism is not due to a liberation of iodids as the result of the action of the

body nitrates upon the iodine salt taken; this does not take place at all; nor are iodids ever changed to iodized albumin in the organism, but they circulate only as alkaline iodids. He considers the condition due to a flooding of the organism and the absorption by its component parts of the alkaline iodids; the condition is therefore not iodism but iodalkalism. This goes to show that the slower the iodids are absorbed the less chance there is for iodism. This can be accomplished by giving the drug in mucilaginous combinations as they prevent medicine from penetrating rapidly. The total daily doses should be divided into as many small portions as possible and the greater the patient's idiosyncrasy the smaller and more frequent the doses. Iodids may be given by enemas, iodized fats or iodipin injections may take the place of the alkaline iodids. Iodipin by the mouth has been found to produce iodine rashes, but when given hypodermically, it never does because of the very slow absorption by this method. Lesser considers the iodipin method very mild, and one that can be employed a very long time. [E.L.]

Potassium Iodid and Iodin in Glycerin Solution for Hemorrhoids.—For many years Preissman,¹ of Odessa, has obtained good results according to the nature of the case, with the following 2 solutions:

	Gm.—Dec.
Potassium iodid	2.0
Pure iodin	0.2
Glycerin	35.0

M. Every hour as directed.

	Gm.—Dec.
Potassium iodid	5.0
Pure iodin	2.0
Glycerin	35.0

M. Each hour, until relieved, then at longer intervals.

[T.H.E.]

The Medicinal Treatment of Pulmonary Tuberculosis.—Buerger¹ says that of the organic phosphorus preparations, especially the lecithins and glycerophosphates, are absorbed in the intestines and augment the albumin deposits. They hardly act as specifics against tuberculosis. In any event, the glycerophosphates are preferable to lecithin, as it is saponified in the intestines. [E.L.]

Salipyrin Poisoning.—Dumstrey,² after having frequently prescribed salipyrin in large doses, and never noting any unpleasant symptoms after its use, considered it an excellent antirheumatic. He reports 3 cases, in which tachycardia, dyspnea, flushing, free sweating, and a sensation of impending death appeared after comparatively small doses, 1 gm. (15 gr.); there was dilation of the pupils, *ad maximum*, and in 2 cases unconsciousness for some hours. On account of these unpleasant occurrences he warns against too liberal use of the drug, and insists that idiosyncrasies should be carefully noted. [E.L.] [This warning applies to all synthetic preparations. S.S.C.]

Treatment of Carcinoma with Röntgen Rays.—P. v. Bruns⁴ concludes from his studies of the röntgen treatment for carcinoma that the great majority of all cancers are not amenable to this treatment, that the carcinomas lying immediately beneath the skin give better results, but the success is usually an incomplete one, and that in cutaneous epitheliomas a complete cure may be expected; whether this is a permanent cure, however, he cannot promise. The studies of the future should have for their aim, in addition to the cure of the cases, the improvement of technic in the direction of permitting rays to penetrate to a greater depth. In the selection of cases those should be chosen in which the amount of time for the röntgen attempt is of no consequence, as in ulcer, or in which operation cannot be performed any more, as in some cases of mammary carcinoma. The latter, even if they cannot be cured, can be made very much more comfortable; the pain disappears, the ulcers scar over, and the masses disappear to some extent. Cases in which the röntgen treatment wastes valuable time should never be trifled with, as an operation may ultimately be

too late. The röntgen rays are no specific, therefore, for the cure of carcinoma, but they promise more than any other agent tried thus far. [E.L.]

DERMATOLOGY

M. B. HARTZELL.

EDITORIAL COMMENT

The Diagnosis of Cutaneous Syphilis ex Juvantibus.—Owing to the prompt and very decided improvement which almost invariably follows the internal administration of the iodids in the skin lesions of late syphilis, the employment of these drugs is commonly regarded as affording a means of diagnosis decisive in doubtful cases; if the suspected lesions show improvement they are syphilitic, if not this diagnosis may be safely rejected. In recent years, however, it has become apparent that this easy method of diagnosis *ex juvantibus* cannot be relied upon, since we have learned that there are other affections beside syphilis which may be favorably influenced by the iodids. A considerable number of observations are now on record showing the favorable effects which follow the internal use of iodid of potassium in actinomycosis and blastomycosis cutis; in both these affections the iodids in large doses produce marked improvement, if they do not bring about an actual cure. Quite recently Beurmann and Ramond have reported a case of multiple mycotic abscess (an abstract of which is given below) in which a complete cure followed the internal administration of iodid of potassium. It is not safe to conclude that because a lesion of the skin shows decided improvement after the use of some one of the iodids, it must necessarily be syphilis. It is quite evident that this diagnostic short cut is not—and never was for that matter—a reliable substitute for the careful study of cases.

REVIEW OF LITERATURE

Secondary Eruptions in Smallpox.—Schamberg¹ calls attention to certain secondary eruptions which commonly occur during the course of variola. During the period of desiccation sparsely distributed blebs occur, more particularly upon the feet and hands. More frequently a reddish vesicular ring forms around the partly desiccated crusts, containing a turbid puriform fluid. These patches spread peripherally as they crust over in the center. When the eruption is abundant it is sometimes accompanied by elevation of temperature, and may be sufficiently extensive to cause death. For this form of eruption the author suggests the term *impetigo variolosa*. Boils and subcutaneous abscesses are common complications of smallpox; cutaneous gangrene occasionally happens. Secondary septic rashes resembling scarlatina or measles occur in a certain proportion of cases during the later stages of the disease, the scarlatiniform eruption being most common. These secondary rashes are sometimes accompanied by elevation of temperature.

Acute Contagious Pemphigus in the Newly Born.—Maguire² reports a small epidemic of contagious pemphigus occurring among newborn children in an institution known as the Richmond Lying-in Charity. Out of a total of 20 infants born in this institution between September 10 and October 23, 18 were affected with a more or less extensive bullous eruption which caused the death of 8 of the infants. Twelve of the 18 cases were attended by the same midwife, whom the author believes conveyed the infection from case to case. In the great majority of the cases the bullas began upon the neck and chin, spreading thence to the trunk. The epidermis over large areas exfoliated, leaving a red, raw, weeping surface. In 9 instances the mother, other children, and those who washed the soiled clothes were infected. In the fatal cases, in addition to the eruption, there were symptoms of acute toxemia. In these infants the groins and lower abdomen were much affected, and

extension to the umbilicus followed, through the unhealed surface of which, as the author believes, general infection occurred. Fluid from the bullas submitted to bacteriologic examination showed *Staphylococcus pyogenes aureus* only.

Anthrasol.—Sack³ relates his further experience with this coal-tar derivative, which he brought to the notice of the profession in 1896. In pruriginous conditions of the skin it has never failed to afford relief. It may be employed pure, in solution, in salves, in oils, pastes, and soaps; it is also miscible with glycerin jelly. In general pruritus, because of the danger of absorption, it should be used in moderately weak solutions—about 10%—in alcohol or in acetone. In pruritus of limited extent, such as pruritus ani, or in itching, circumscribed eczema, it may be used in a strength of 20% to 30%, or even pure. In pruritus ani the undiluted anthrasol acts brilliantly, and mixed with glycerin it has proved a sovereign remedy. The fluid mixtures are especially indicated in itching affections of the scalp. These are likewise useful in the milder forms of psoriasis and psoriasiform seborrheic eczema; in the severer forms of the first named, salves, with the addition of sulfur, resorcin, salicylic acid, etc., are more effective. Instead of the salves made up with vaselin, the author prefers the following:

Anthrasol	3.0
Lanolin	3.0
Ung. glycerin, q.s. ad.	30.0

Multiple Subcutaneous Abscesses of Mycotic Origin.—Beurmann and Ramond⁴ report a hitherto undescribed form of abscess which they believe due to a fungus. Clinically the case was characterized by the presence of small tumors resembling in their size, form, and consistence, parasitic cysts. Histologic examination, however, showed that they were neither hydatid nor cysticercus cysts, but abscesses with a thick membrane, containing grumous, odorless pus. Bacteriologic examination revealed a fungus the same in all the lesions, growing upon certain media with characters always the same. As this fungus, which consisted of spores and mycelium, was the only one which developed, the authors conclude that it was the cause of the abscesses. Attempts at inoculating it upon animals were followed by negative results. The patient was completely cured by the administration of iodid of potassium internally.

The Relationship between Psoriasis and Affections of the Joints.—Lipman-Wulff⁵ reports a case of psoriasis associated with extensive arthritis. The patient was a man who, up to the age of 52, was perfectly healthy. At 52 years of age he began to suffer from psoriasis, and two years later an affection of the joints appeared, which began with pain and swelling of the interphalangeal articulations. Notwithstanding the employment of baths, massage, and salicylic preparations, the joint affection extended so that the patient, at the end of a year, was no longer able to follow his usual occupation. The psoriasis continued, sometimes better, sometimes worse, but as the patient expressly stated, uninfluenced by the arthritis. The author is of the opinion that there is not sufficient ground for belief in the existence of a special psoriatic arteritis, such as has been described by some French authors, but that psoriasis and chronic joint affections may occur in the same individual without being necessarily related.

The Etiology of Acne Vulgaris.—Gilchrist⁶ has found a definite bacillus, which he names *Bacillus acnes*, in a large number of typical acne lesions obtained from 86 patients. Pure cultures were obtained from 62 lesions taken from 29 patients. This bacillus, which was shown to be pathogenic in mice and guineapigs, in smears is short and thick, but in cultures often becomes much longer and thicker, and in old cultures assumes distinct branching forms. It grows on acid glycerin agar, forming a pultaceous, easily movable mass. The serum of patients suffering from acne produces clumping of the bacillus, from which it is inferred that a specific toxin produced by the bacillus is absorbed by the blood, producing a specific agglutinin. The author thinks it possible that the anemia, constipation, headache, and disturbances of digestion, which are commonly regarded as predisposing causes of acne, are actually the

results of the continued absorption of toxins produced by the enormous numbers of bacilli present in all the lesions.

Psoriasis of the Mucous Membrane of the Mouth.—Oppenheim¹ reports the case of a man, 53 years old, who, in addition to the ordinary skin lesions characteristic of psoriasis, presented certain other peculiar lesions upon the mucous membrane of the mouth. The tongue showed nothing abnormal, but upon the mucous membrane of both cheeks and of the hard and soft palate were oval, bluish-white, sharply-limited, and elevated patches. The patches upon the palate differed somewhat from those on the cheeks, one showing a finely stippled surface, while the other was quite smooth and yellowish-white in color. Syphilis and leukoplakia were excluded on clinical grounds, and the diagnosis of psoriasis confirmed by microscopic examination of tissue excised from one of the patches.

Alopecia Congenita Familialis.—A. Krauss² reports the cases of 3 children of one family, all of whom were born with thick hair, but who lost their hair shortly after the birth, and no hair has reappeared since, although the oldest is over 4 years old. The skin looks atrophic, thin, and smooth; no follicle openings are visible. The eyebrows, nails, and teeth are normal. Microscopic examination showed neither hair-substance, root, nor papilla; rudimentary hair-bulbs and follicles exist. The hair-muscles and sebaceous glands are rudimentary and abnormal in position, but the sweat-glands are normal. [E.L.]

Treatment of Local Hyperidrosis.³—Hyperidrosis limited to the feet, hands or axillas demands energetic treatment. Local cold baths with astringent preparations and perfumed with various aromatics may be used frequently. Baths of formol or potassium permanganate cause fetid sweating of the feet to disappear rapidly. Formol is used in the proportion of 1 dessertspoonful to 1 quart of water. Potassium permanganate is used as follows:

Potassium permanganate 10 gm. (5iiss)
Distilled water 300 gm. (3ix)

One dessertspoonful to 1 quart of water.

Brocq uses the following liquid diluted with 1 or 2 times its volume of water:

B naphthol 5 parts
Glycerin 10 parts
Alcohol 100 parts

After the lotion the area is dried carefully, then powdered with talc, starch, bismuth subnitrate or the following, which is used in the English army against bromidrosis:

Salicylic acid 3 gm. (45 gr.)
Starch 10 gm. (23 dr.)
Powdered talc 87 gm. (3 oz.)

Brocq uses the following:

Salicylic acid 3 gm. (45 gr.)
Powdered alum } of each 5 gm. (75 gr.)
B naphthol }
Sodium borate } of each 10 gm. (23 dr.)
Powdered starch }
Powdered talc 67 gm. (2 oz.)

The same powders may be used under the arms and between the thighs.

About every 8 days a few drops of the following liquid may be dropped between the toes:

Red oxid of lead 1 gm. (15 gr.)
Solution of lead subacetate 29 gm. (1 oz.)

By the use of this treatment, the most rebellious forms of local sweating were cured rapidly. [L.F.A.]

A Rare Congenital Condition of the Skin.—L. R. Mueller⁴ reports 2 cases of congenital disturbance of the vasomotor nerves of portions of the skin. The first patient presented in portions of the upper half of the body an extreme marble whiteness, alternating with dark bluish-red spots; the entire left lower half of the body was the seat of a venous hyperemia. The condition was more marked in winter than in summer; in warm weather it almost entirely disappeared. The condition is not due to a spinal or ganglionic lesion, even

though it is arranged in segments, but rather to developmental alteration in the nerves of the cutaneous vessels. Such alterations usually occur in segmental arrangement. [E.L.]

The Cause of Baldness.—Morris Schein¹ claims that baldness begins (1) in that part of the scalp which lies close to the basement membrane; (2) at the point of muscle-pull when the frontal and occipital muscles contract together; (3) when the nutrition of the scalp suffers intensely and early. In women the muscle-pull which brings about an intense stretching of the scalp on the basement membrane is ineffective, and the nutrition of the frontal and vertical regions does not suffer as much as in man. In the old, the change in formation of the skull which is associated with stretching and poor nutrition of the scalp, readily brings about an extension of the baldness. The growth of the hair as well as the falling of the hair depend upon changes in nourishment of the scalp. While in the falling out of the hair the nourishment of the scalp is diminished, it is increased in the growth of the hair. The diminution of the nutrition of the scalp is caused by an intense stretching of the same on the aponeurosis. In cases of falling out of the hair, as well as its growth, there is a mechanical cause upon which the change in nutrition of the scalp, the hair, and the growth and disappearance of the hair depend. [J.H.W.R.]

Differential Diagnosis between Syphilis and Drug Exanthems resembling Syphilis.—C. Berliner² describes briefly a number of cases of cutaneous eruptions occurring in his and other physicians' practices, which resembled and were treated for syphilitic eruptions. They were caused by iodids, bromids, antipyrin and numerous other drugs belonging to these groups. He recommends that in all acutely occurring exanthems the food products and drugs likely to produce them should be inquired for; acutely occurring eruptions are more likely to be due to drugs than to syphilis. Itching, burning, fever, etc., are rare in syphilitic eruptions. Mistakes are especially frequent when the eruption exists near the border of cutaneous and mucous membranes. Of positive value in the diagnosis before starting antisyphilitics, is the placement of the patient on absolute diet for a short time. Drug eruptions and those due to food will disappear almost as quickly as they came. [E.L.]

Leukoderma in a Boy of Eleven.—This case, reported by R. B. Ness,³ who observed it in the Royal Hospital for Sick Children in Glasgow, is interesting because of the positive history that the disease began when the boy was but little more than 6 years of age. The boy was small for his age, being 46 inches high, and weighing but 55 pounds when seen by the writer. Broadly speaking, the skin of the whole body, except the palms of the hands, soles of the feet, and the scalp was affected. The skin between the leukodermic patches was quite markedly pigmented, of a brownish color. Cases of this disease beginning before the age of 10 are rare. There is no distinct history of nervous disorder in the family of the patient, but 5 other children died of pulmonary affections between the ages of 1 and 3 years, and 1 other has a congenital malformation of the eyes. [A.G.E.]

Diabetes and Skin Diseases.—E. Saalfeld⁴ states that the interdependency of skin diseases and diabetes has been overestimated. He discusses those occurring only with diabetes (xanthoma diabeticum, bronze diabetes, diabetic gangrene and papillomatous diabetic dermatitis). They all occur very rarely. All other dermatoses are accidental complications of diabetes; they are always more persistent and grave than in nondiabetics. Very often the disease is not improved by any means until the patients are put on antidiabetic regimen. The skin disease may be the precursor of diabetes. He advises routine urine examination, therefore in every patient suffering from a skin disease. Psoriasis and leukoplakia have never been associated in his experience with diabetes. Syphilis and diabetes may coexist accidentally, or the glycosuria be produced by the former; antiluetic treatment in the latter case will usually remove the glucose from the urine. A family tree of a family in which diabetes and carcinoma coexist is reproduced. [E.L.]

\$5.00 YEARLY.

The new sanitary sleeping cars adopted by the Pullman Company have come none to soon, and unless the rules and standards have been made after thoroughgoing scrutiny of sanitary experts, it is hardly likely that the ideal has been realized. Reform in sleeping cars was, of course, most needed, but in other cars it is emphatically called for. All have been constructed seemingly with the purpose of being cleansed and disinfected with the greatest difficulty, and of harboring most securely, parasites and the germs of disease. As in the common bed, so here, every part should be made of metal that is possible, all corners and cracks done away with; the plushes, velvets, and soft materials replaced when possible by materials more easily cleaned, etc. Then, the great desideratum in all beds, seats, etc., is ease of taking every thing apart, with complete purification by water, heat, or disinfectants at stated and frequent times. All this leaves untouched, the problem of cleansing the freight and stock cars, which, from the moment they are put in service to the day they are consigned to the scrap-heap, are allowed to become the conveyors of unimaginable filth and the breeding places of any disease germs that can nest in them.

Baby-farming and Baby-murder.—If the newspaper reports are to be trusted, there has recently been unearthed in Philadelphia the details of the most hideous and systematic criminality as regards the traffic in and murder of infants. There are good reasons for believing that this city is not by any means the most guilty, and that careful search would find the revolting practice of buying and selling children's bodies and lives, even burning the living or dead victims in furnaces, is not unknown elsewhere. It would doubtless be unjust to charge all "maternity homes" with criminality equal or approaching that which has appeared in the coroner's office, but proofs abundantly sufficient have been brought to light to warrant the demand that all such institutions must be placed under rigid public surveillance and government. The horrors that may be connected with them are the logical outcome of any permitted secrecy, and so long as human nature remains what it is, there should be the strictest safeguards of publicity, license, and oversight. Even the best must be watched, and even the best may give unconscious evidences that there is a leaning to immorality. In a

circular letter of a "maternity home," before us as we write, and giving the best of references (do the referees ever see?), there is the squinting line that "a liberal percentage is allowed physicians who send us patients."

Practical Application of the "Side-chain" Theory.—The address delivered last week by von Ehrlich before the American Association of Pathologists and Bacteriologists has a practical bearing in establishing a close relation between his "side-chain" theory and clinical medicine. This study of the therapy of diseases caused by the trypanosome was entered upon in the hope of discovering an agent which would not only kill the parasite, but the latent forms also, thus preventing relapse. Following up the action of stains upon the parasite, Ehrlich discovered that one of the congo stains, benzopurpurin, acted as well as arsenic, although a few relapses still occurred. This led to the endeavor to produce a more soluble compound with the same qualities, and by introducing further H_2SO_4 radicals in the benzol ring he succeeded in obtaining a new substance, which he has named "trypanroth," and which possesses marked specific properties, the action being most favorable in mice infected with the parasite of the South African disease of horses. Injected into mice one to three days before infection it confers immunity, though not of long duration. This is possibly through the stain causing some reaction on the part of the body, which is followed by the production of substances which kill the parasites. The address was most interesting and timely; there are many, especially among those not directly engaged in experimental work, who are demanding practical results from the work along the lines which come under Ehrlich's theory, and, not seeing these results, have lost faith. Whether the "side-chain" theory stands or falls, it has been, and still is, one of the most valuable working hypotheses which medicine has ever followed, and this new line of definite, synthetic chemistry applied to medicine has evidently grown directly from the basis of the "side-chain" theory.

Journalistic rivalry and jealousy has sometimes strange ways of manifestation. Readers of several journals may be puzzled to discern the truth among the contradictory views expressed in different editorial and review columns concerning an operation, method of treatment, person, or book. But these apparently un-

accountable contradictions are soon recognized as motivated upon something else than those honest individual opinions which necessarily exist even when the writer speaks or pretends to speak judicially and professionally. Two equally good authorities will take irreconcilable sides for or against the same thing, book, or person, the one finding good or partial good, the other finding the whole matter too contemptible to treat with patience or decency. Occasionally an understanding of the incongruity may be found in the fact, generally forgotten or unknown, that editorial jealousy and personal prejudice may dictate the published opinion. The extent to which the abuse grows is mystifying to those uninitiated in the secrets of journalism, but is most instructive to those conversant with the real conditions. A successful professional, editorial, or journalistic rival is a natural mark for envious detraction, and so long as imagination exists in journalistic circles, it is not at all necessary to wait or search for opportunity. Of course this is poor journalism, and finally comes to naught, but in the multiplication of commercial medical journals it has long been well understood that editorial opinions and reviews are frequently personal and partisan, with a thin veneer of assumed science and professionalism calculated to deceive the trusting.

Jacob's Voice but Esau's Hands.—If the editorial review or editorial opinion concerning a book or medical proceeding is in a medical journal commonly called a "house-organ," the property of a manufacturing or publishing firm, the judgment given may be biased by commercial interests and contemptibly contemptuous in its wording. Of course, there are honorable exceptions; and every editor and publisher would repel any insinuation that there is any ulterior influence of a mercantile nature at work to mould editorial utterance. But the disclaimer is not credited by those who have attentively watched the action of certain editorial minds for a number of years. The publisher of medical textbooks who issues a journal as a "feeder" to his main business, usually establishes by implication if not direct command a "policy" for that journal of praise for his writers and of depreciation or attack upon the works of rival publishers. If it so happens that his editor, in carrying out this policy, has opportunities for private vengeance in "reviewing" the work of a professional or journalistic rival, then, in the trust that the personal motive may be overlooked in a mere extension of the house's policy, the result is scornful depreciation or vitriolic attack. These facts are of axiomatic acceptance by publishers, who still send "review copies," knowing that a review will gain in bitterness because the book to be disparaged had to be bought; although instances are on record of books having been reviewed and savagely attacked without even the cursory reading which would have prevented the reviewer's blunders. It is an ancient story in the world of general literature and criticism, but it is a pity that it should be so often repeated in medicine. The editors, upon whom the ultimate responsibility for the condition rests, may justify themselves with the good old proverb, *Wessen Brod ich ess dessen Lied ich sing*.

State Supervision of Private Hospitals.—With the growth of luxury there has arisen a condition which soon or late will demand the attention both of the profession and of the law makers. Private hospitals have of late years been enormously multiplied. Carried on by honorable physicians no blame can be attached to them or their owners, although they have often been criticised by the younger men as vastly increasing the already too great tendency toward medical monopolies. When the public hospitals depend upon private pay-patients for a considerable share of their income the private hospitals may become harmful rivals and go a long way toward crippling their usefulness and public service. But a still greater danger is clearly manifest and is causing a bitter criticism which may indeed develop into scandal. To be frank in reference to the matter it is said that, shielded by the advantages of secrecy and by the example of the properly conducted private hospitals, quackish and even criminal institutions are also multiplying. It would be strange if without any governmental oversight or license the disreputable should not seize upon the immunity from control and carry on what are really abortionist and extortion practices. A few exposures would doubtless serve the useful purpose of bringing all to the bar of legal control and license. Such licensure and State regulation would be welcomed by those which are professionally conducted. It would be well however if this ideal could be realized before any concealed disgraces are brought to light.

The victory of the lowered deathrate—and as a rule it is still lowering—is one for which the medical profession may well be proud. Only ten years ago a statistician said that, "a deathrate of less than 18 in the thousand in a city of more than a million population is a sanitary impossibility." It is with proper pride that the Chicago Health Commissioner quotes the rate for his city in 1903 as 15.34, and if the midyear estimate were made upon the same basis as in London, it would be 14.53. This result of preventive medicine, splendid as it is, and *de facto* better than that of London, is in truth outdone by the much larger and older city, where the sanitary difficulties are of course much greater. For the year 1903 the English Registrar-General estimates the deathrate at 15.62. In Chicago, however, there has been an increase during the last two years, the cause of which is traced by Dr. Reynolds to the greater severity of the winter, the average temperature for last winter being 7° or 8° lower than in 1901-2. Berlin's honor of second place to Chicago is now taken from her by London, while other large cities are far behind. The deathrate is the thermometer of civilization. A commissioner of health of a great modern city is the greatest saver of lives, or the greatest death-dealer of any man in the world.

Against the legalization of osteopathy in New York, that veteran general in the war against quackery, Dr. Frank Van Fleet, chairman of the committee on legislation of the Medical Society of the State of New York, is now waging a worthy battle. A bill has been intro-

duced in the Legislature, entitled, "An Act to Define and Regulate the Practice of Osteotherapy." This bill defines "osteotherapy" as follows:

The practice of osteotherapy is defined to be a system, method or science of healing disease without the use of drugs or medicine of any kind. It is based upon the proved laws of anatomy and physiology, and comprises scientific and thorough knowledge of the structure and functions of the human mechanism, to apply certain organic laws and natural remedial resources, within the human organism itself, and by means of scientific manipulations and adjustment, assist nature, in harmonious accord with its own mechanical principles, activities and processes, to recover from displacements, derangements, obstructions and processes, and to regain normal equilibrium of form, action and function, thus restoring to the patient normal health and strength. The word "osteotherapy" is derived from the Greek ("osteon," bone, and "therapeia," nature, healing). The word "osteopathy" is a correction of the word "osteopathy," which latter means, translated from the Greek ("osteon," bone, and "pathy," suffering) bone suffering. The word "osteotherapy" embraces the science so-called osteopathy, the practice of massage and Swedish movements to its fullest extent, and any one practising the latter sciences, under those or different names, shall come under the jurisdiction of this act."

It is difficult to imagine this as a serious effort to secure legislative enactment, for the definition makes one laugh; but we must assume that the gentleman who introduced the bill was not actuated by the desire to amuse his colleagues. The measure goes on to provide for a board of examiners, appointed by the regents of the University of the State of New York, for examination and registration fees, and so on. If all physicians would write to the members of the Senate Judiciary Committee opposing this bill, its fate would not be long in doubt. Aid is needed from all who are endeavoring to protect our professional standards. We give in another column the Committee's reasons why the practice of osteopathy should not receive any legal sanction.

To Increase the Efficiency of the Medical Department of the U. S. Army.—A bill has been introduced in Congress, approved by Surgeon-General O'Reilly, the Secretary of War, and others, which should command the approval of the profession and all the aid it can bring to bear for its passage. The Medical Department of the army at present suffers from three serious defects of organization which handicap its efficiency in time of peace and render impossible any efficient expansion in time of war. These are: A commissioned personnel entirely inadequate to perform the medical service of the army even in time of peace; insufficient inducement in the way of pay and promotion to attract the most desirable class of young physicians to enter the corps; no satisfactory means of expansion to meet war conditions and special needs in time of peace (epidemics, "little wars," etc.). The only means of expansion heretofore existing, the employment of contract surgeons to supplement the insufficient commissioned personnel, has always been wasteful and unsatisfactory, and has now become absolutely impractical because of the recent decision that the contract surgeon not being an officer, obedience to his orders cannot be enforced even in the case of the enlisted men of the

Hospital Corps. The aim of the bill is to remedy these defects by providing for a Medical Corps and a Medical Reserve Corps sufficient to meet the demands of the law and of the conditions in which our government finds itself. There has been much criticism of the regulations in the British army, but Surgeon-General O'Reilly cites the following figures, which show how far we are from giving relative and adequate honor and support to our medical officers:

Percent of Corps having general and field rank:	
Medical Corps, U. S. Army, 1903	25.3%
Medical Corps, U. S. Army, 1898	38.2%
Medical Corps, U. S. Navy	33.6%
Medical Corps, British Army	48.8%
Engineer Corps, U. S. Army, excluding second lieutenants	38.5%

Protozoa and Disease.—A very entertaining and instructive article on the above topic is that in the *April Century*, by Gary N. Calkins, adjunct professor of zoology at Columbia University. The purpose of the writer is to enlighten the general public regarding the unfamiliar term protozoa, a term made prominent by recent medical discoveries and a term "which is confused by the average reader with bacteria, microbes, and germs as a new kind of unknown, fearsome thing." He has succeeded admirably in presenting elementary facts relating to these lowest forms of animal life, known since 1675, and their importance in the etiology of disease. The statements regarding the wellknown malaria parasite and the less wellknown varieties causing, or supposedly causing, yellow fever, smallpox, and scarlet fever, are conservative and reliable; opportunity is seized to emphasize the value of vaccination. On the whole, this is one of the best of the popular medical articles that have appeared in recent lay publications. Such papers merit commendation, as they are a valuable means of educating the public in the causation and prevention of disease. What good might be accomplished if our daily papers occasionally printed articles of this stamp instead of the worse than senseless twaddle evolved from the inner consciousness of nonscientific "penny-a-liners" who "write up" medical happenings! But we are not pessimistic; the attitude of the press in general is encouraging. Physicians should foster this tendency toward scientific enlightenment of the people at large.

Extension of the Registration Area and Improvement of Vital Statistics.—According to a circular issued by the Public Health Committee of the American Medical Association, that Committee is cooperating with the U. S. Census Bureau and U. S. Public Health Service, as well as with committees from the American Public Health Association and other national sanitary organizations, in endeavoring to bring about a more satisfactory registration of vital statistics in this country. This work has been especially commended by joint resolution of Congress and by resolutions of the American Medical Association passed at its last session at New Orleans. It is hoped that all State Medical Societies, especially those in States not now having satisfactory registration of mortality statistics, will

appoint Committees on Vital Statistics at their next annual meetings, as requested by the resolutions of the American Medical Association, to cooperate with the Public Health Committee and to urge the passage of proper legislation at the next sessions of the State Legislatures. The following are the necessary provisions for a registration law for deaths:

1. Deaths must be registered immediately after their occurrence.
2. Certificates of death (standard form) should be required.
3. Burial or removal permits are essential to the enforcement of the law.
4. Efficient local registrars are necessary.
5. The responsibility for reporting deaths to the local registrar should be fixed.
6. The central registration office should have full control of the local machinery, and its rules should have the effect of law.
7. The transmission and preservation of returns should be provided for.
8. Penalties should be provided.

Committees may correspond directly with Dr. Cressy L. Wilbur, Expert Special Agent of the U. S. Census Bureau, Lansing, Michigan, who represents the Government authorities interested in the extension of registration and is in direct touch with the Public Health Committee in its labors in pursuance of the resolution of the Association. Dr. Wilbur will advise with the committees of any State in regard to the details of a proper registration bill, and will, when necessary, personally appear before medical societies, health officers' associations, legislative committees, etc., as may seem to be desirable for the purpose of advancing this work.

The Cigaret Habit.—A magistrate of New York, is strongly opposed, with good reason, to the use of cigarettes by boys. He says that in the last 6 months more than 300 boys have been arraigned before him for greater or less crimes, and of that large number 98% confessed to smoking cigarettes. Perhaps the other 2% also smoked them but did not care to acknowledge the fact. Cigarets are mentally and physically injurious to boys, whatever effect they may have on men.

Discoverer of the Laryngoscope.—The *British Medical Journal* says: A venerable figure is that of Manuel Garcia, the discoverer of the laryngoscope, who completed his ninety-ninth year March 17. He was born at Madrid, in 1805, and was the brother of Malibran and the teacher of Jenny Lind and many other famous singers. Till a few years ago he was actively engaged in voice training. He discovered the means of observing the interior of the larynx in 1854, and in the following year read his memorable paper, entitled "Physiological Observations on the Human Voice," before the Royal Society of London. His observations were made on himself, and in his examinations he used 2 mirrors—a small one fixed on a long stem for introduction into the pharynx, and a large one which served at once to throw the light—it was that of the British sun!—on the small mirror and to enable the observer to see the image formed thereon. The discovery was treated with indifference, and for years the laryngoscope was spoken of by superior persons in this country as a physiologic toy. Garcia's paper fell into the hands of Turck, of Vienna, who, after a short trial, declared that "he was far from entertaining too sanguine hopes about the employment of the laryngeal mirror in practice." Fortunately, the mirrors which Turck threw aside were borrowed by Czermak, the physiologist, of Budapest, who quickly saw to what good use they might be put. He substituted artificial illumination for the uncertain light of the sun. The light was reflected and concentrated by a large ophthalmoscopic mirror. He had mirrors of different sizes, and finally the art of laryngoscopy was presented in a practicable shape to the medical world in a paper which appeared in the *Wiener medicinische Wochenschrift* of March 27, 1858. Among the honors conferred on Manuel Garcia in recognition of his discovery is the degree of Doctor of Medicine, which was given him *honoris causa* by the University of Königsberg.

AMERICAN NEWS AND NOTES

GENERAL.

The First Woman Physician.—An exchange says: A recent report from the University of Halle mentions the interesting fact that this institution was the first in Germany to give the medical degree to a woman. It was in 1754 that the university created a daughter of Dr. Leporin of Halle a "doctor medicinae." Her scientific studies had been carried on under the direction of her father, but in the university halls she defended a set of theses that secured her these academic honors. She is no doubt the pioneer of the modern university movement among the women of Germany, having as early as 1742 published a work entitled "Gründliche Untersuchung der Ursachen, die das weibliche Geschlecht vom Studiren abhalten, darin deren Unerheblichkeit gezeigt wird, und, wie möglich, nötig und nützlich sey, dass dieses Geschlecht der Gefahrheit sich befeisse." This first medical doctor of Germany died in 1762. We remark, by the way, that the University of Königsberg, in which the reaction against women students that set in about 2 years ago in the Prussian universities went so far that the medical faculty practically excluded women entirely, has, in a measure, relented. The medical department now again admits women to anatomic work, but not with the men.

NEW YORK.

Reasons of the Committee of the Medical Society of the State of New York why Osteopathy, Osteotherapy, and other Peculiar Methods of Treating Disease should not Receive Special Privileges.—1. There are no methods of counteracting the results of disease, or of remedying or correcting physical defects, known to science, which are not known and practised by qualified and competent physicians when such methods have in themselves any valuable properties. 2. The practice of medicine, or, to use the more comprehensive term, the treatment of disease, has not reached that degree of perfection where it is possible to say with exactness that a certain remedy is a certain cure under all conditions. Circumstances modify conditions, and it is only after weighing all the conditions present in a given case, and often after consultation with experts in special lines, that the remedy can be selected and properly applied; and even then, under what may seem to be the most favorable conditions, the results are not always satisfactory. Therefore, the State, recognizing how imperfect and uncertain the knowledge of the healing art is, has created a standard of proficiency with which all who desire the right to practise this art must comply. Not that such practitioners may be able to treat certain diseases; not with the idea of creating certain classes of practitioners, but with the single idea that all who hold themselves out as competent to practise the healing art shall have sufficient knowledge to recognize and discriminate the various diseases and defects, and to be familiar with and able to apply the known remedies. The State places in the hands of practitioners of the healing art extraordinary discretionary power; after receiving this power from the State, these practitioners are responsible to nobody but themselves for the conscientious discharge of their duties. It would be manifestly improper for the law-making powers to confer privileges such as these on any but the most competent, in order to make them as little a menace to the community as possible. 3. Osteopaths, or osteotherapaths, claim that the method they employ is not the practice of medicine. The person, be he Supreme Court Judge or an ordinary citizen, who claims that the practice of medicine necessarily implies the giving of medicine or drugs, must have a very limited knowledge of the work of physicians. There are many physicians who have received the privilege from the State to practise medicine, and who would deny they were anything but practitioners of medicine, who rarely resort to drugs in the treatment of the affections they have to deal with. Indeed, it is quite as much the function of the medical practitioner to give advice as it is to give medicine; to apply other forms of treatment, as baths, rubbings, massage, and manipulations, as it is to apply drugs. There is an ever growing tendency to give fewer and fewer drugs in the treatment of disease, but no educated physician would be willing to undertake the treatment of any form of disease if he was denied the privilege of giving drugs and medicines if they seemed to be indicated, or, indeed, to be restricted in his treatment of disease to the employment of any one method. Whether the treatment of disease is the practice of medicine or not, one thing is certain: Osteopaths and osteotherapaths desire the privilege possessed by licensed physicians, that of treating diseases. Not one disease, or any particular class or type of disease; they desire the right to undertake the treatment of all diseases, defects, and infirmities indiscriminately, as physicians do, except that they are willing to be restricted to the employment of one method of treatment. This, as already stated, is in itself sufficient to condemn them as indicating the absence of knowledge of the scientific discoveries of the present time. No conscientious and educated physician would be willing to submit to a restriction of this kind. 4. The so-called theories of the so-called osteopaths or osteotherapaths are positively dangerous. For example: They have recorded themselves at the hearings before the Legisla-

ture of New York and other States, as not believing in the contagiousness of certain diseases, as smallpox, scarlet fever, erysipelas, and so on. With this ignorance, they would not realize the necessity for disinfection, and would go directly from attendance on a case of this kind to deliver a pregnant woman, and the result might be disastrous. The denial of the value of antitoxins, of vaccination, and of the necessity for isolation and disinfection, together with the teaching of doctrines entirely at variance with accepted scientific facts, stamps these people as positively dangerous to the community. That they should ask the State to create a standard for them less rigid than that with which physicians generally have to comply, is evidence itself that their motive is neither honest nor honorable. If osteopaths or osteotherapaths really and honestly believed they were possessed of a knowledge, or had a method of treating diseases superior to the knowledge or methods of other physicians, they would not constantly endeavor to secure the legal right to employ their methods by compliance with a standard less than that already demanded by the State. The logical course to pursue would be to comply with the existing standard, and then demonstrate the superiority of their methods. 5. Osteopaths or osteotherapaths claim an extraordinary knowledge of anatomy and chemistry. If such a claim is a truthful one, it does not stamp the possessors of such knowledge as competent to practise the healing art. A knowledge of physiology and pathology is even more important and necessary. It will not do to say that one does not believe in the accepted views of pathology and etiology unless one has a knowledge of them, and one cannot have a knowledge of these branches unless one has devoted sufficient time to their study to acquire it. If four years of study are necessary to prepare and properly equip physicians, and osteopaths or osteotherapaths can secure the legal right to undertake the treatment of disease after only two years of preparation, some other class of practitioners will doubtless appear and urge, with equal reason and justice, that only one year of preparation is necessary to fit one to practise their method properly. It will not do for the State to discriminate; if any standard is necessary at all, it should be made to apply to all alike. Either this must be done, or, in justice to all practitioners of the healing art, all standards should be abolished, and the field thrown open to all comers. The latter course would be the best for the doctors, but not so good for the community. The public, generally, can have but a limited knowledge of what is best in the way of remedies and methods in the treatment of disease. For its own protection the State creates medical laws, and, instead of lessening the requirements of these laws at the request of all sorts of fakirs who may come along, it would be better to make the requirements more rigid, and make the penalty for violation of the common law so severe and so easily enforced that quacks and charlatans of all kinds would keep clear of the State of New York.

PHILADELPHIA, PENNSYLVANIA, ETC.

State Hospital for Inebriates.—From Des Moines, Iowa, under date of March 18, comes the news that the bill creating a State hospital at Knoxville for the treatment of inebriates has passed the Senate. It was amended to meet the objections on constitutional grounds, and passed without opposition. It gives the former Industrial Home for the Blind at Knoxville for the purpose of an inebriate home, and appropriates \$125,000 in addition. New buildings are to be erected and additional ground purchased. The bill also provides for the government of the institution and the method of sending inebriates or those addicted to excessive use of narcotics to the institution for treatment. Such treatment is not to last more than 3 years.

SOUTHERN STATES.

Pension Medical Examiners.—It is asserted that one reason why the U. S. Pension Commissioner desired to establish a service or age pension really was to relieve the service of 4,500 doctors, who act as pension examiners throughout the country, and it is claimed they not only acted in their official capacity but are likewise active political canvassers. Whether this report has any foundation in fact is uncertain.

WESTERN STATES.

Mortality of Michigan During February, 1904.—The total number of deaths reported to the Secretary of State for February was 3,389, an increase of 263 over the preceding month. The death rate rose from 14.7 in January to 17.1 for February. By ages there were 523 deaths of infants under 1 year of age, 201 deaths of children aged 1 to 4 years, and 1,158 deaths of elderly persons 65 years of age and over. The principal increase of the month was for the latter class. Important causes of death were as follows: Tuberculosis of lungs, 189; typhoid fever, 42; diphtheria and croup, 67; scarlet fever, 32; measles, 21; whooping-cough, 27; pneumonia, 487; influenza, 195; cancer, 128; accidents and violence, 175. Diphtheria was somewhat less prevalent than last month, while pneumonia and meningitis increased, the latter especially nearly doubling in amount. There were 3 deaths from smallpox, 1 in Detroit, 1 in Frankenlust township, Bay county; and 1 in Oregon township, Lapeer county. One death from chickenpox was reported from Detroit.

FOREIGN NEWS AND NOTES

GENERAL.

Bubonic Plague in Pretoria.—Information from Pretoria, March 23, says: The plague has appeared here. One death therefrom occurred today. It was announced from Johannesburg, March 20, that an outbreak of the bubonic plague had occurred in the Indian coolie section, and that 30 deaths from the disease had been reported since the preceding Thursday, March 17.

The Tenth International Congress of Ophthalmology will convene in Lucerne, September 13, 14, 15, 16, and 17, 1904. Only those papers will have the right to be discussed which shall have been printed and sent beforehand to all members of the Congress. Manuscripts should be sent to Professor Dr. Mellinger, Bale, before May 1. Those desiring full information can obtain it from Walter H. Jessop, M.B., 73 Harley street, London; George Mackay, M.D., 20 Drumsheugh Gardens, Edinburgh; Henry R. Swanzy, M.B., 23 Merriensquare, Dublin; Dr. DeSchweinitz, 1401 Locust street, Philadelphia, U. S. A.; Dr. Coote, Quebec, Canada; Dr. Alfred Osborne, Alexandria, Egypt.

OBITUARIES.

John Metcalfe Polk, an assistant visiting physician at Bellevue Hospital, in New York City, March 29, aged 28. He was graduated from the Sheffield Scientific School of Yale University, receiving the degree of Ph. B. in 1898. In the following year he began the study of medicine and was graduated from the Cornell University Medical College in 1899, ranking second in his class. He served as interne in the second medical division of Bellevue Hospital until January, 1902, when he went abroad to take a post-graduate course, chiefly in Vienna. On his return to New York City, in December, 1902, he was appointed an instructor in the Cornell University Medical College, and at the time of his death was instructor in medicine and physical diagnosis. He was later appointed to the position of adjutant assistant physician in Bellevue Hospital. During the past winter he had been conducting some experimental work upon the hemostatic action of the blood in infectious diseases. This is practically completed, and it is hoped that the results interrupted by his death may be collected and published.

Professor A. B. Arnold, a former resident of Baltimore, at San Francisco, March 29, aged 85. He was graduated in medicine at the Jefferson Medical College, and was professor of principles and practice of medicine at the Baltimore College of Physicians and Surgeons from 1875 to 1898, when he was made professor emeritus of that department. He was widely known as an author of treatises on surgery and medicine and was as equally eminent as a translator of old Hebrew and Arabic writings.

Stephen P. Truex, a wellknown practitioner of Brooklyn, suddenly March 31, while performing an operation in the Bushwick Central Hospital, aged 48. He was graduated from the Long Island College Hospital, in 1891, and was visiting gynecologist of the hospital and lecturer on obstetrics and gynecology in the Post-Graduate Hospital in Manhattan. He was a member of the King's County Medical Society.

Aaron R. Gleason, in Keene, N. H., March 4, aged 68. He was graduated from the University of Georgetown, Washington, D. C., in 1864. He served as a hospital steward and assistant surgeon during the Civil war. He was a member of the American Medical Association, a member of the New Hampshire Legislature in 1897, and fellow of the New Hampshire Medical Society.

Elisha Peckham Clarke, in Hope Valley, R. I., March 17, aged 70. He was graduated from the Medical School of Maine, at Bowdoin College, Brunswick, in 1863. Was a fellow of the Rhode Island Medical Society and served as its president in 1895 and 1896. He was also president of the South County Medical Society in 1878, and served as surgeon during the Civil war.

George H. Butler, of New York City, March 28, aged 62. He was graduated from the Bellevue Medical College, in 1869. He was a member of many medical societies, including the Medical Society of the County of New York, the New York Physicians' Mutual Aid Association, the New York Academy of Medicine, and the New York Chemists' Association.

George H. Hammond, of Freeport, L. I., March 29, aged 58; a graduate of the Medical Department of the New York University, in 1872. He was surgeon to the Nassau Hospital, L. I., member of the Queens-Nassau Medical Association, and of the Associated Physicians of Long Island.

Fred. A. Fanyo, of Watseka, Ill., March 22, aged 26. He was graduated from the University of Illinois, Chicago, in 1903; was an interne at Cook County Hospital and assistant to the Chair of Clinical Diagnosis in the University of Illinois.

Henry C. Gemmill, in Markle, Ind., March 18. He was graduated from the Rush Medical College, Chicago, in 1868. He was a member of the American Medical Association, Hunter County Medical Society, and Indiana State Medical Society.

Washington Hopkins Baker, of Philadelphia, April 2, aged 52. He was graduated from the medical department of the University of Pennsylvania, in 1875. He was active in hospital work and was identified in the military service.

F. Campbell, in Kansas City, Kas., March 17, aged 47. He was graduated from the University of Michigan, Ann Arbor, in 1883, and served for eight years as superintendent of the Ossawatimie State Hospital.

Frank H. McIlroy, in Providence, R. I., March 18, aged 26. He was graduated from Tufts College Medical School in 1903, and was assistant pathologist to the Rhode Island Hospital.

Abraham H. Hunt, in Wooster, Ohio, March 18. He was graduated from the Long Island College Hospital, Brooklyn, in 1862, and was a member of the American Medical Association.

Maurice Silk, resident physician of Hart's Island, died March 28, in New York City. He was graduated from the New York College of Physicians and Surgeons, in 1902.

John Chester Lyman, March 29, aged 53. He was graduated from the Harvard Medical School, Boston, in 1872. He retired from practice nearly 20 years ago.

Edward N. Gerrard, in Mesa, Ariz., March 18, aged 67. He was graduated from the medical department of the University of Iowa, Keokuk, in 1861.

Jeremiah S. Hetrick, in New Freedom, Pa., March 27, aged 65. He was graduated from the Baltimore College of Physicians and Surgeons, in 1877.

A. O. Heiberg, of Rushford, Minn., at Northfield, Minn., March 18. He was graduated from the Jefferson Medical College, Philadelphia, in 1893.

E. P. Noel, of Chicago, Ill., in Phoenix, Ariz., March 29. He was graduated from the Starling Medical College, Columbus, Ohio, in 1890.

J. G. Cannon, in Yuba City, Cal., March 17, aged 78. He was graduated from the Physio-Eclectic Medical College, Cincinnati, in 1876.

Myron Northrup, of Port Huron, Mich., March 15, aged 67. He was graduated from the Geneva (N. Y.) Medical College in 1859.

A. P. Birch, of Toledo, Ohio, March 21, aged 67. He was graduated from the Western Reserve University, Cleveland, in 1888.

S. J. Seyfert, in Pine Grove, Pa., February 14, aged 61. He was graduated from the University of Pennsylvania, in 1871.

Frank I. Phillips, in Escanaba, Mich., March 22. He was graduated from the Detroit Medical College, in 1882.

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended April 1, 1904:

SMALLPOX—UNITED STATES.

		Cases	Deaths
Colorado:	Denver.....Jan. 30-Feb. 27...	22	1

Reported

Changes in the Medical Corps of the U. S. Army for the week ended April 2, 1904:

DECKER, GEORGE M., contract dental surgeon, is granted leave for one month.

BREWER, ISAAC W., contract surgeon, is granted leave for twenty days with permission to apply for an extension of ten days.

STEDMAN, First Lieutenant CHESTER J., assistant surgeon, is granted leave for fifteen days, to take effect upon his being relieved from duty at the Army Medical School, Washington, D. C.

DELOFFRE, First Lieutenant SAMUEL M., assistant surgeon, is granted leave for fourteen days, to take effect April 1, with permission to apply for an extension of seven days.

SHOOK, First Lieutenant JAY RALPH, assistant surgeon, upon the completion of the course of instruction at the Army Medical School, will proceed to Fort Leavenworth for duty, to relieve First Lieutenant Ralph S. Porter, assistant surgeon. Lieutenant Porter will proceed to Fort Niobrara for duty.

MILLER, First Lieutenant REUBEN B., assistant surgeon, upon the completion of the course of instruction at the Army Medical School, will proceed to Fort Screven to relieve First Lieutenant Harry L. Gilchrist, assistant surgeon. Lieutenant Gilchrist will proceed to Washington, D. C., and report at the U. S. General Hospital, Washington Barracks, for duty with Company of Instruction No. 1, Hospital Corps.

JUENEMANN, First Lieutenant GEORGE F., assistant surgeon, upon the completion of the course of instruction at the Army Medical School, will proceed to Fort Ringgold for duty, to relieve James E. Shellenberger, contract surgeon. Contract Surgeon Shellenberger will proceed to Fort Sam Houston for duty.

MILLER, First Lieutenant EDGAR W., assistant surgeon, upon the completion of the course of instruction at the Army Medical School, will proceed to Fort Clark for duty, to relieve Fred T. Koyle, contract surgeon. Contract Surgeon Koyle will proceed to Fort Bliss for duty, to relieve William T. Baird, contract surgeon. Contract Surgeon Baird will report by letter to the surgeon-general of the Army for annulment of contract.

TEFT, First Lieutenant WILLIAM H., assistant surgeon, upon the completion of the course of instruction at the Army Medical School, will proceed to Fort Snelling for duty, to relieve Captain George A. Skinner, assistant surgeon. Captain Skinner will proceed to Fort Harrison for duty, to relieve Captain George J. Newgarden, assistant surgeon. Captain Newgarden will proceed to San Francisco, Cal., for transportation to the Philippine Islands.

The following named assistant surgeons upon the completion of the course of instruction at the Army Medical School, will proceed to the posts designated for duty: First Lieutenant Robert E. Noble, U. S. Army General Hospital, Washington Barracks; First Lieutenant Gideon McD. Van Poole, Fort Stevens; First Lieutenant James I. Mabey, Fort Casey; First Lieutenant Percy L. Jones, Fort Monroe; First Lieutenant Fred W. Palmer, Jefferson Barracks; First Lieutenant John B. Bosley, Fort Thomas; First Lieutenant Chester J. Stedman, Columbus Barracks.

HARVEY, Colonel **PHILIP F.**, assistant surgeon-general, leave granted February 26, is extended one month.

MORSE, First Lieutenant **ARTHUR W.**, assistant surgeon, is granted leave for one month from about March 18.

SILBER, First Lieutenant **JOSEPH F.**, assistant surgeon upon the completion of the course of instruction at the Army Medical School, and the expiration of the leave granted him March 15, will proceed to Fort Logan for duty.

KNUST, **JOHN G. J.**, sergeant first class, and **DAVID ACKER** and **ISAAC COHN**, privates, who have been on duty in connection with dietary experiments at New Haven, Conn., when their services are no longer required at that station will be sent to the Army General Hospital, Washington Barracks, for temporary duty with the Company of Instruction No. 1, Hospital Corps, and to join the first detachment of the hospital corps to be sent from that station to the Philippines Division.

FRITZ, **CHARLES J.**, and **PATRICK H. JOHNSON**, privates, first class, of the same detachment at New Haven, Conn., when their services are no longer required at that station will be sent to Fort Jay for duty; and Private **Barnard Bates**, now in confinement at Fort H. G. Wright, is relieved from further duty at No. 332 Temple street, New Haven, Conn., and assigned to his present station.

HENRY, **JOSEPH N.**, contract surgeon, is granted leave for one month and twenty-three days, on surgeon's certificate, being an extension of seven days' ordinary leave.

WILLIAMSON, Captain **LLEWELLYN P.**, assistant surgeon, is relieved from duty at Jefferson Barracks, and will proceed to St. Louis, Mo., and report to Dr. W. P. Wilson, chairman Philippine Exhibit Board, Louisiana Purchase Exposition, to supervise sanitary matters in the Philippine village and the care of the sick among those connected with the Philippine exhibit.

DEWITT, First Lieutenant **WALLACE**, assistant surgeon, will proceed from New Haven, Conn., to St. Louis, Mo., upon the completion of the special duty to which he was assigned in letter from the adjutant general's office of September 11, 1903, and will report to Major **Richard W. Johnson**, surgeon, in charge of the medical department exhibit, for duty as his assistant.

HUTTON, First Lieutenant **PAUL C.**, assistant surgeon, is granted leave for five months on surgeon's certificate.

VAN POOLE, First Lieutenant **GIDEON MCD.**, assistant surgeon, is granted leave for one month from about April 6.

Changes in the Medical Corps of the U. S. Navy for the week ended April 2, 1904:

EDGAR, **J. M.**, surgeon, detached from the *Wisconsin*, and ordered to the *Monadnock*—March 30.

TRAYNOR, **J. P.**, assistant surgeon, detached from the *Frolic*, and ordered to the *Albany*—March 30.

OMAN, **C. M.**, assistant surgeon, detached from the *Monadnock*, and ordered to the *Frolic*—March 30.

MARCOUR, **R. O.**, assistant surgeon, detached from the *Dixie*, and ordered to duty with the Marine Battalion at Guantanamo, Cuba—March 31.

HIGH, **W. E. G.**, assistant surgeon, detached from the *Constellation*, and ordered to the Midway Islands for duty with the Marine detachment at that place, sailing from San Francisco, Cal., April 8, via the *Supply*—March 31.

Changes in the Public Health and Marine-Hospital Service for the week ended March 31, 1904:

WASDIN, **EUGENE**, surgeon, granted leave of absence for one month from April 1, 1904, on account of sickness—March 30, 1904.

ROSENAU, **M. J.**, passed assistant surgeon, detailed to represent Service at meeting of Tuberculosis Committee, College of Physicians, Philadelphia, Pa., March 28—March 26, 1904.

CUMMING, **H. S.**, passed assistant surgeon, granted leave of absence for ten days from April 5—March 25, 1904.

LAVINDER, **C. H.**, passed assistant surgeon, granted leave of absence for two days from March 25—March 26, 1904. Granted three days' extension of leave of absence from March 31—March 29, 1904.

GRUBBS, **S. B.**, passed assistant surgeon, granted ten days' extension of leave of absence from March 31—March 28, 1904.

BILLINGS, **W. C.**, passed assistant surgeon, granted leave of absence for two months and three days from April 30, 1904, with permission to go beyond the sea—March 28, 1904.

RICHARDSON, **T. F.**, assistant surgeon, detailed to attend conference of State Health Officer and County Health Officers of Texas at Austin, Texas, March 31—March 29, 1904.

AMESSE, **J. W.**, assistant surgeon, granted leave of absence for two months and fifteen days from May 1—March 26, 1904.

BOGGESE, **J. S.**, assistant surgeon, granted leave of absence for two days from March 30—March 29, 1904.

Boards Convened.

Board convened to meet at Washington, D. C., to consider the construction or purchase of boarding steamers for the quarantine stations at San Francisco, Cal.; Fort Townsend, Wash.; also to consider type of launch for boarding or inspection of vessels at the Key West Quarantine and at Havana, Cuba; also to consider the feasibility of repairing the hull of the launch *Spray* at the Delaware Breakwater Quarantine, and placing new motive power therein.—Detail for the board: Assistant Surgeon-General A. H. Glennan, chairman; Assistant Surgeon-General W. J. Pettus, Assistant Surgeon-General H. D. Geddings, recorder.

Board convened to meet at Baltimore, Md., April 4, 1904, for the physical examination of officers of Revenue Cutter Service for promotion.—Detail for the board: Surgeon H. K. Carter, chairman; Assistant Surgeon C. W. Wille, recorder.

Board convened to meet at San Francisco, Cal., April 4, 1904, for the physical examination of an officer of the Revenue Cutter Service.—Detail for the board: Passed Assistant Surgeon W. G. Stimpson, chairman; Assistant Surgeon Carl Ramus, recorder.

SOCIETY REPORTS

THE AMERICAN ASSOCIATION OF PATHOLOGISTS AND BACTERIOLOGISTS.

Fourth Annual Meeting, Held in New York City, April 1 and 2, 1904.

[Specially reported for *American Medicine*.]

The meeting of the Association was the most successful of the four thus far held. The attendance was large. The presence of prominent clinicians proved the interest which clinical medicine has in this special field. The speakers were held strictly to the time limit assigned them on the program, so that the papers were clear, concise, and strictly to the point. Discussion was limited to five minutes, and owing to the large program, only a small number of the papers of most immediate interest called forth any discussion at all. Herr Geheimer Medicinalrath Professor Dr. Paul Ehrlich, Frankfurt-am-Main, Germany, was the guest of the Association, and gave an address on Friday afternoon.

Officers.—Simon Flexner, of New York, was elected president for the ensuing year, with James Ewing, of New York, vice-president. Herbert U. Williams, of Buffalo, as treasurer, and Harold C. Ernst, of Boston, as secretary were reelected.

The Technic of the Operation Known as Eck's Fistula.—J. E. SWERT (Philadelphia). The paper was of a purely technical nature, describing the various methods which have been used in establishing an artificial anastomosis between the portal vein and the vena cava inferior, with a description of some new instruments used for the operation.

A Pathologic Study of Amaurotic Family Idiocy.—WILLIAM G. SPILLER (Philadelphia) discussed in detail the cases of this disease which he has found in the literature, and described the pathologic findings in a case. The disease presents the picture of a peculiar and widespread degeneration of the central and peripheral nervous system. The cells of the spinal cord and of the brain centers are swollen, and the dendrites have disappeared. The nerve-fibers in the various tracts are also degenerated, but the motor tracts show evidences of being first attacked. The nerve cells are primarily diseased; it is not of toxic origin, and probably not an acquired disease.

Hemolysis in Human Urine.—ROGER S. MORRIS (Ann Arbor), starting from the fact that many toxic products of bacterial origin, as well as definite chemico poisons, can be found in the excretions of the body, took up the study of the urine in various diseases, especially in pernicious anemia. If the destruction of blood cells is due to bacterial hemolysins which are absorbed from the intestine, these products could possibly be found in the urine. The results were negative. In some cases of pernicious anemia the urine showed hemolytic properties, but this phenomenon was not constant, and could not be brought into any relation to the extent of the anemia.

Specific and Nonspecific Agglutinins.—WILLIAM H. PARK (New York) gave the results of his work upon the specific individual agglutinins and the group agglutinins of the dysentery organisms. The main object of the paper was to point out several reasons why various observers have differed in their results, these differences being due to the time necessary for the production of the different agglutinins in the immune animal. The specific agglutinins appear first, but if the immunization with a single organism be continued, the immune serum will develop agglutinins which will act upon other types of that group, and will also protect against other types.

Degeneration of the Spinal Cord Produced by Repeated Injections of Cultures of Bacillus Coli Communis of Low Virulence.—G. A. CHARLTON (Montreal) read by J. G. Adami. The repeated injection of this organism produces first an anemia, and later causes degenerative changes in the spinal cord, of an ascending nature, which finally attacks the bulbar centers. The sciatic nerve from such animals shows some degeneration; the cord shows some myelin sheath degeneration; the upper lumbar region especially is riddled with vacuoles. The process is, in general, a diffuse degeneration confined to the posterior and lateral columns. Only living cultures produce the anemia and these degenerative changes in the cord, while filtrates of cultures, or cultures killed by heat, or the feeding of cultures, produce no effect.

The Nature of Blood-plates.—JOSEPH H. PRATT (Boston) concludes from his study of the literature that different observers have not described the same thing, for example some have described biconcave bodies, while others have found biconvex forms. The forms described by Bizzozero are the normal platelets, they are flat, composed of a central granular mass, surrounded by a clear margin. The normal plates never suggest extrusion from an erythrocyte. The forms described by Arnold are degeneration products; they are irregular in size and form and contain hemoglobin. The normal blood-plates can be preserved by solutions of sodium metaphosphate, which is the method used by Pratt. The function of these bodies is not clear, since they are not present in the blood of a peptonized animal, which blood does not coagulate, but there are also none present in the blood of an animal immunized against peptone, which blood will coagulate.

The Nonspecificity of the Somatogenic Cytotoxins.—R. M. PEARCE (Albany) directed his work toward a solution of the questions, To what extent does a morphologic specificity exist? Or have various cells, of different morphologic characteristics, molecular groups in common, which, when injected into an alien species, cause the production of one and the same receptor group? To what are the varying results obtained by different workers to be ascribed? The method employed was to immunize rabbits against emulsions of the kidney, liver, adrenal and pancreas of an untreated dog, against emulsion of the same organs from the body of a dog which had been transfused with large quantities of saline solution to remove all blood and serum, and against dog's urine, serum and bile. The results were practically the same in all cases. An antiserum obtained from an animal treated with the emulsions of washed organs has no effect when injected into normal dogs; the kidney shows some indication of nephrotoxic action, but this can be produced by a serum of an animal immunized against other than renal cells, and a specific nephrotoxic serum also shows action upon organs other than the kidney. The antiserum obtained by immunization against unwashed organs has marked action *in vivo*, an action which is to be ascribed to its hemolytic activity. Serums obtained with both washed and unwashed organs, as well as from animals immune to serum, urine, and animals treated with very small amounts of alien blood, is agglutinative and hemolytic. An antible serum produces focal necroses of the liver. Pearce concludes that the question of specificity depends upon the chemic composition of the cell, and not upon its morphologic constitution. Most of the results obtained with cytolytic serums are to be ascribed to their hemolytic power.

On Agglutinins.—B. X. BUXTON and VICTOR C. VAUGHAN (New York) discussed the variations in agglutinability; freshly isolated cultures do not agglutinate as readily as older cultures. The effects of heat upon the agglutinins were studied, and experiments were made with the absorption of the different agglutinins.

Coagulation Time of the Blood of Nephrectomized Rabbits.—S. J. MELTZER and W. SALANT (New York) noted that the blood of a nephrectomized rabbit did not coagulate for 75 minutes, and this paper gives the results of a study of the phenomenon. The results from a large series of animals showed that normal rabbit's blood, clots after an average time of 7.9 minutes; the blood of nephrectomized rabbits clots after an average time of 23.3 minutes. According to the time after the operation when the test is made, three phases may be noted, a gradual increase of the coagulation time up to a maximum, and then a fall. Tissue fluid hastens the clotting of this blood, as in normal bloods. In discussion, Levin says that the coagulation time is increased after the removal of the adrenals, and Pearce notes the same increase of coagulation time after the removal of one kidney, or after the ligation of the vessels of the kidney. The blood also clots less readily after the injection of cytolytic serums.

Decapsulation of the Kidney: An Experimental Study.—I. LEVIN (New York), by means of a specially constructed apparatus, which encloses the kidney and transmits any changes in the size of the organ to a recording mechanism, reaches the conclusion that any powerful influence which acts upon the kidney acts longer upon the decapsulated than upon the normal organ; the capsule is therefore probably an elastic covering, which expands and contracts with the needs of the organ, acting, in a way, as a safety valve. The question arises then, whether the therapeutic value of decapsulation is not less than that of nephrectomy without decapsulation. In discussion, MELTZER points out the relation of the capsule to the innervation of the organ. He notes further the importance of the capsule of an organ in preventing the direct spread of an infection.

Coagulation of the Blood and Thrombosis.—LEO LOEB (Philadelphia) reached these conclusions: It is possible to obtain thrombi composed mainly of agglutinated blood-plates in animals whose blood has been made incoagulable by injection of leech-extract. It is therefore probable that agglutination of cellular elements and not formation of fibrin is the primary factor in thrombosis. An active influence of the endothelium of bloodvessels inhibiting the coagulation of the blood cannot be shown to exist. The serum of the dog has an inhibiting influence on the effect of tissue coagulins which themselves accelerate the coagulation of peptone plasma. This inhibiting effect is probably a specific one. Organs undergoing processes inside the body which are similar to autolysis have still an accelerating effect upon the coagulation of the blood. Ankylostoma contains a substance strongly inhibiting the coagulation of the blood. This substance is produced principally or entirely in the anterior part of the body. It is probably one of the causes of the anemia of ankylostomiasis. The material covering the intestinal mucosa has a strongly accelerating effect on the coagulation of the blood, being thus able to restrict hemorrhages. The pancreas possesses the least coagulative power of all organs examined, and is therefore relatively favorable to hemorrhages.

A Method for the Differential Staining and Counting of the White Blood Cells.—B. ONUF (Soyea, N. Y.) says the method consists in staining the cells in the ordinary mixing pipet, and counting in the ordinary Zeiss chamber. The stain, which is described as giving brilliant differential results, is as

follows: Equal parts of (1) 12% aqueous solution of formalin; (2) 1% aqueous solution of NaCl, c. p.; (3) 0.5% aqueous solution eosin (yellowish); (4) Unna's polychrome methylene-blue. The staining solutions should not be too old.

The session is closed with demonstrations:

F. B. MALLORY (Boston), "Demonstrations with the microscope of neuroglia, myoglia and fibroglia fibrils."

C. F. MARTIN (Montreal), "Pathologic demonstrations."

Xanthoma: A Histologic Study of the Lesions of the Nodular Form of the Disease, with Lantern Demonstrations.—JOSEPH MCFARLAND (Philadelphia). The paper was read by McCONNEL (Philadelphia), and was a detailed description of the cellular findings in the nodes of this rare disease. The disease probably arises from some abnormal condition of the connective tissue, the cells of which multiply and later are infiltrated with fat.

The Morbid Anatomy and Etiology of Avian Tuberculosis, with Lantern Demonstrations.—VERANUS A. MOORE (Ithaca) exhibited a number of lantern slides illustrative of the gross and microscopic lesions of avian tuberculosis, and described the characteristics of the avian bacillus. The results of the inoculation of guinea-pigs, rabbits, and pigeons with the organism were negative. A series of experiments with the inoculation of fowls with bovine and human tuberculosis were also negative. He does not know the origin of the disease, which often assumes economic importance, but he scouts the idea that it is contracted from either equine, bovine, or human tuberculous matter.

The Development of the Lymph-nodes in a Hemangioma Cavernosum of the Orbit.—ALDRED S. WARTHIN (Ann Arbor). A long-standing, pulsating tumor of the orbit in a woman of 45, showed upon microscopic examination the structure of a cavernous angioma; it is characterized throughout by the presence of lymph-follicles. The lymphoid tissue forms by a progressive infiltration of the connective tissue, trabeculae with lymphoid cells. The tissue of the tumor is comparable to that of the hemolymph glands. A similar formation of lymphoid tissue has been observed in a few cases of macroglossia.

The Occurrence of Myeloid Changes in the Hemolymph Nodes.—ALDRED S. WARTHIN (Ann Arbor). A case of hemorrhagic anemia showed the presence of atypical tissue in the retroperitoneal hemolymph nodes. The tissue shows the characteristics of bone marrow, with the bone marrow giant cells, the eosinophiles and neutrophils. Warthin thinks that metaplasia explains this atypical lymphoid formation.

The Eosinophilous Transformation of Lymphocytes; the Formation of Eosinophiles in the Hemolymph Nodes; the Relation of Eosinophiles to Hemolysis.—A. S. WARTHIN (Ann Arbor). In hemolytic processes the eosinophiles increase greatly in number in the hemolymph nodes; they probably develop from mononuclear lymphocytes, the granules representing the remains of the intracellular lysis of the erythrocytes. Warthin's papers were all illustrated with lantern slides.

Demonstration of the Ova of Distoma Westernmani (by courtesy of Dr. A. D. MacKenzie, of Portland, Ore.).—E. R. LECOUNT (Chicago) stated this was the first case of parasitic hemoptysis described in this country. It occurred in a Japanese who came to this country from the province of Okayama, Japan. Infection with this trematode is very common in this province of Japan, and the disease has been thoroughly studied by several Japanese observers. The disease occurs in two forms, the pulmonary and the cerebral. In both cases cysts are formed, with thick walls which are made up of the tissues of the host. Bronchiectasis, and pneumonia are the chief symptoms.

Epithelial Tumors of the Skin and Mucous Membrane, with Special Consideration of Carcinoma Basocellulare.—JOSEPH C. BLOODGOOD (Baltimore) gave this as a preliminary report, with lantern demonstrations. The demonstrations consisted of a large number of slides of the gross and microscopic findings in cases of benign tumors, especially of the face, which have been cured by operation. The paper is a contribution to the surgical pathology of operable tumors, under which class the tumors arising from the basal cells of the epidermis are to be placed. The classification is that of Krompecher. Of 468 cases, 16% were of this basocellular type, and were most common on the face. The use of caustics seems to aggravate the growth, while a complete removal gives assurance of freedom from recurrence.

Primary Glioma over the Coccyx with Recurrence and Metastases.—F. B. MALLORY (Boston) gave this lantern slide demonstration of sections of a tumor from a woman 44 years of age, with metastases in the right groin, and later, recurrence in the right groin, and at the original site, and metastases in the left groin. The tumor has the structure of both an alveolar and a papillary carcinoma, in general, but is marked by the presence of the typical fibrils of a glioma. The origin is to be sought in the remnants of the neural canal over the coccyx.

An experimental study of the therapy of the diseases caused by the trypanosome was the title of an address by GEHEIMRATH EHRLICH. Certain substances are already known which will kill the parasites, but latent forms are always left in the blood, and relapses occur after a longer or shorter period. Ehrlich began to experiment upon the action of stains on the parasites, and finally found one of the congo

stains, benzopurpurin, which acted as well as arsenic, but a certain number of the mice used in the experiment suffered later from relapses. Ehrlich then tried to produce a new substance by introducing further H_2SO_4 radicals into the benzol ring, thus producing a more soluble compound, which he has named "Trypanroth." This substance is now found to possess marked and specific properties; it will save mice infected with the parasite of the South American disease of horses. This action is most favorable in mice, but Ehrlich hopes that further modification will produce a compound which will act as favorably in other animals. The study is at present more of theoretic interest. Trypanroth does not kill the parasites in the test-tube; injected into mice one to three days before infection it confers an immunity. He concludes that the stain causes some reaction on the part of the body, which is followed by the production of substances, which kill the parasites. If mice are infected, then treated with the trypanroth, they are found to have become more resistant to reinfection, but this resistance does not last very long. This phenomena is possibly analogous to malaria as seen in man; the body becomes immunized by the products of the malarial parasite, which are broken up by quinin, but this immunity soon disappears and reinfection occurs from the latent forms, which persist in spite of the use of quinin.

The Influence of Salts on Lytic Serum.—In this paper LUDVIG HEKTOEN (Chicago) gave the results of the work of Hektoen and Ruediger upon the effect of the addition of certain salts to serum. The hemolytic properties of the serum can be removed by such additions, while the serum regains its original properties if the salt be neutralized by the addition of the proper combination. It is thought that the work may possibly have some bearing upon infection, since it is possible that the complements are affected by the production of salts by the action of bacteria within the organism.

A study of the blood of normal guineapigs was read by S. H. BURNETT (Ithaca), and comprised blood counts and morphology.

W. L. R. COPLIN (Philadelphia) demonstrated pathologic specimens mounted in gelatin upon glass plates.

The Group of Dysentery Bacilli.—WILLIAM H. PARK (New York) gave this study of the group relations of the various members of the dysentery group, making use of anti-serums, and comparing the results with the classification of the group by the use of maltose and mannite media. The result of the work seems to have been that the grouping by means of the sugar media corresponds in general to the grouping obtained by means of the study of the specific agglutinins. As in the case of the colon group, certain organisms can be found which possess characteristics of more than one group. Discussing the paper, Dr. His says that maltose is not as dependable as dextrose in the classification of the dysentery group.

Studies upon Antistreptococcus Serum.—D. H. BERGEY (Philadelphia) gave this paper as a preliminary report upon the work. Antistreptococcus serum has been obtained which has agglutinative and slight protective properties, but in which no bacteriolytic action can as yet be demonstrated. The agglutinative and protective action is exerted not only upon the organism used for the immunization, but upon other streptococci as well.

Differences in Precipitins Produced by the Tubercle Bacilli.—EDWARD R. BALDWIN (Saranac Lake). Tubercle bacilli were extracted by special methods, and the extracts were then injected into rabbits. The serum of these rabbits gave positive results with such extracts, causing a distinct precipitation. The study is a contribution to our knowledge of the differences in bacterial products.

Immunization against Tubercle Bacilli.—E. L. TRUDEAU (Saranac Lake) was invited to describe the results of his experiments. His experiments were directed toward the question: Is the living organism necessary to the production of an immunity? Twelve guineapigs were inoculated with an attenuated living culture, and 12 with the same culture killed by heat. After a certain period the pigs were then inoculated with living virulent cultures. Control animals were also inoculated. At the present time, 60 days after the death of the last control, 7 of those injected with living organisms are still alive. At the time the last control died, 4 of those injected with the killed bacilli were still alive. Trudeau concludes that the injection of dead cultures produces a certain degree of immunity, but not such a high degree as that caused by the injection of the living organisms. These are not absolutely immune to tuberculosis, but the lesions which they show are much less extensive than in the control pigs, or than in the pigs injected with the dead cultures. In the discussion WELCH pointed out the possibility that the living organisms may produce under the influence of the body substances which differ from those produced in cultures.

Some Observations with Tuberculins from Different Races of Tubercle Bacilli.—S. B. WOLBACH (Boston) prepared tuberculins from the human and the bovine bacilli, and then tested their action upon animals inoculated with both varieties of the organism. He concludes that his experiments have given no evidence of any specificity. Treatment with tuberculin seems to have a favorable effect, increasing the length of life for an average of 14 days over the life of the controls. No essential differences can be seen in guineapigs between the disease produced by the human bacillus and that

produced by the bovine bacillus. In the discussion TRUDEAU notes that the avian bacillus does not produce as strong a tuberculin as the other species, and that attenuated human organisms will produce as powerful a tuberculin as virulent organisms. Theobald Smith refers to his work upon the difference in the reaction of old cultures of the human and the bovine bacilli, and points out that this difference in reaction should cause some differences in the substances produced in the tuberculin.

The Comparative Morphology of Vaccine Bodies.—JAMES EWING (New York) demonstrated with colored lantern slides the bodies which have been variously described as parasitic forms, in vaccinia, the lesions of the cornea following the injection of diphtheria toxin, in variola, the skin of a frog, and in measles. His opinion, subject to change, is that these bodies represent changes in the nucleoproteids, and that they offer as yet no definite evidence of being of a parasitic nature.

The Effect of Certain Blood-serums (Leukocytic) on the Ameboid Motion of Leukocytes.—HENRY A. CHRISTIAN (Boston) gave a study of normal and artificial leukocytotoxins, using the effect upon the ameboid motion of the white cells as an index of the activity of the serum. Natural leukocytotoxins occur less widely than the normal hemolysins, but when present in a serum, as also the leukocytotoxins of a specific serum, the ameboid motion is instantly stopped. The same result is obtained whether the animal be immunized against washed or unwashed liver or kidney, as when the unwashed spleen is used to furnish the leukocytes for the immunization. A specificity in that antiserum acts only upon the white cells of the same species, could be demonstrated. The main conclusion of the paper is that the morphology of a cell is an imperfect index of the chemie composition of the receptor construction of that cell.

Hemolymphotoxin was read by A. S. WARTHIN for Mr. HARRO WOLTMAN (Ann Arbor). The effects upon the blood itself of such serums is the same as that described in the work of Flexner and Bunting upon the same subject. Wolman concludes that there are no specific hemolymphotoxins.

The Experimental Production of Liver Necroses by means of Hemiagglutinins.—R. M. PEARCE (Albany) stated that local necroses may be caused in one of three ways, by the direct action of toxic substances of bacterial origin, by a plugging of the capillaries with the phagocytic cells described by Mallory, or by a plugging of the capillaries with agglutinated masses of red cells, which is the mechanism of the necroses described by Pearce. The agglutinating serums can be produced by the injection of washed and unwashed organs, the injection of serum and urine, of defibrinated blood, and more especially, the injection of bile. The necroses occur principally at the periphery of the acini, i. e., in the portal circulation; there are no phagocytes concerned, and no proliferation of the endothelium occurs. These agglutination thrombi can be demonstrated in the blood of the portal vein a few minutes after the injection of the antiserum. The liver seems to recover from the effects of such necroses, so that after repeated injections it is found to be normal, showing that such a process has no part in the production of chronic lesions. The same form of necrosis can be produced by the injection of the hemiagglutinins of bacterial origin.

A simple method of isolating from water forms which agglutinate with typhoid serum by J. GEORGE ADAMI and J. A. CHOPIN (Montreal) and a simple method of demonstrating the presence of bacteria in the mesentery of normal animals by A. G. NICHOLLS (Montreal) were read by Dr. ADAMI.

FOURTH SESSION.

A Bacillus Agglutinated by High Dilutions of Typhoid Serum; Isolated from Water.—O. KLOTZ (Montreal). The paper was read by Dr. ADAMI. It forms a contribution to the group of bacilli described by Sternberg, which stand between the coli and the typhoid group.

A Case of Glioma in the Sella Turcica was reported by E. E. SOUTHWARD and FREDERICK H. HOWARD (Boston). The tumor was from the brain of a woman of 48 who had suffered for many years from a progressive impairment of vision; later, attacks of coma developed, and death occurred in the fourth attack. The autopsy revealed a tumor in the sella turcica which had encroached upon the surrounding tissues. No akromegaly was present. Microscopically the tumor is composed of cells arranged as in certain sarcomas, but the tissue is distinguished by the presence of glioma fibrillas. The cells are provided with cell processes, which in some cases can be seen to be continuous with the fibrils. A careful examination of the tissue of the entire tumor in its relation to stains, etc., shows that the oldest portion of the growth is in the posterior part of the pituitary body.

An Epizootic among Rats and Rabbits Due to a Hitherto Undescribed Flagellate Micrococcus.—O. KLOTZ (Montreal) gave a detailed description of the cultural characteristics and lesions produced by this new organism.

The Bacteriologic Examination of Blank Cartridges.—DAVID H. DOLLY (Cleveland), in this paper, made a very complete study of this subject of active summer interest. The result of the cultural and inoculation experiments showed that the wads contain *Bacillus aerogenes capsulatus* in a large proportion of cases, while the tetanus bacillus can be found in a

few instances by inoculation experiments. The powder is usually sterile.

The Role of Staphylococci in Systemic Infections.—EMANUEL LIBMANN (New York) made this contribution to our knowledge of the bacteriology of the circulating blood. Libmann has found the aureus in 26 cases during life. Seven of the patients recovered. A detailed description of the cases followed, with a discussion in regard to the place of the aureus and its relation to the albus.

The Further Differentiation of the Flagellas and Somatic Agglutinins.—H. G. BEYER and A. L. REAGH (New York) presented the results of further work along the line indicated by the title, the results of which were first described by Theobald Smith, and a confirmation of the work of Joos. It is possible to separate in an immune serum as well as in a culture, by means of heat, two different substances; in the culture one substance produces a flagellar agglutinin, the other an agglutinin for the cell bodies. In the serum are the two distinct agglutinins.

A case of hemangiosarcoma of the skin of the finger was reported by W. MCN. MILLER (Columbia). The paper was not finished in the time allowed.

The Properties of the Serum of Animals Treated with Infusions of Adrenal Glands.—N. GILDERSLEEVE (Philadelphia) stated that the purpose of the paper was to determine if any specificity can be demonstrated in the serum of an animal treated with such injections, and to what the effect of such serums is due, if the effect is not a specific one. By using washed organs Gildersleeve was able to demonstrate that a specific antiserum is not formed, the only effect of such a serum being to cause a greater fall of temperature than the injection of normal serum. Very small amounts of defibrinated blood will cause the production of a specific hemolytic antiserum, and it is probable that the results formerly described as specific are to be ascribed to the hemolytic action of the serum.

Farm Colony Advocated for Victims of Drink and Drugs.—The International Order of King's Daughters and Sons makes an appeal for funds with which to establish a farm colony on Long Island for the redemption of victims of alcoholism and the drug habit. Through the efforts of the Women's Auxiliary, a free clinic for the treatment of poor patients has been established at Madison Square Church House. The aim of establishing a farm colony has grown out of experiences in connection with the work there, where many poor in the last stages of alcoholism come to be treated.

The Human Brain.—An exchange says: In order to determine the average weight of the human brain, Professor Marchand and of the Pathological Institute of the University of Marburg has, during the past 7 years examined 1,234 specimens. In men between 15 and 50 the average weight of the brain is 1,400 gm., in women 1,300 gm. Only 30% of the males showed a weight higher than 1,450 gm., and 20% less than 1,300 gm. In women, 25% had brains weighing less than 1,200 gm., but 55% had brains weighing from 1,200 gm. to 1,350 gm. The difference in weight is not conditioned by the difference in bodily size, for men and women of the same size and weight show this difference as well as others. Marchand asserts that the weight of the brain at birth is doubled in the first three-quarters of a year, and is trebled before the completion of the third year, after which period the rate of increase is much less. In men, full development is reached at the age of 18 to 20 years; in women, at 16 to 18 years. In childhood the ratio of the development of the brain and of the body is the same in males and females, independent of age, until the body has attained a length of 70 cm.

Is Fish Good for the Brain?—The popular idea that fish nourishes the brain is pronounced fallacious by the *Lancet* (London). Furthermore, that paper asserts that it is doubtful whether any given food in common use contains constituents which have a selective action, or the property of ministering to one part of the body more than another. Says the writer: "As a rule, when a food is assumed to have specific reparative properties—as, for example, a so-called brain or nerve food—the fact really is that such food is easily and quickly assimilated to the body's general advantage—in a word, in such a case repair quickly overtakes waste and a real purposeful nutrition and restoration are accomplished. The administration of such elements as phosphorus or iron in medicine is, of course, a different matter, but these elements are evenly distributed in the materials of a daily diet. It is often stated that fish is a food which ministers particularly to the needs of the brain because it contains phosphorus. As a matter of fact, fish does not contain more phosphorus than do ordinary meat foods, and it certainly does not contain it in the free state. The notion that fish contains phosphorus had no doubt its origin in the glowing or phosphorescence in the dark. This phosphorescence is due not to phosphorus at all, but to microorganisms. The belief, therefore, that fish is a brain food is just about as reasonable as the idea that because a soup is thick and gelatinous 'it will stick to the ribs,' or as sensible as the celebrated advice to Verdant Green to lay in a stock of Reading biscuits to assist his reading. Fish, of course, is excellent food, partly because of the nourishing nature of its constituents and partly because of its digestibility. But it is in no sense a specific for brain or nerve."

CLINICAL NOTES AND CORRESPONDENCE

FRACTURE OF THE HUMERUS OF A CHILD IN ITS DELIVERY.¹

BY

J. T. MOORE, M.D.,

of Galveston, Texas.

Associate in Medicine, Medical Department, University of Texas, Galveston.

I suppose fracture of the humerus of a child in its delivery is not a very rare accident, but as textbooks say but little about it, I have decided to report the following case. These are not difficult cases to treat, but at the same time they occasion much concern upon our part, especially if it is our first accident of this sort.

CASE.—Mrs. T., a primipara, aged 20. Full term, nothing unusual in her labor. The head was delivered in the right occipitoiliac anterior position. The cord was found to be wrapped around the neck, but this was easily removed. The right arm was doubled back of the child in a peculiar fashion, and I hooked my finger over the forearm and brought it back to a proper position. After freeing the arm, instead of leaving it to deliver itself, I attempted to bring it down by slight traction with my finger in the bend of the elbow. I used but little force, but there was a distinct crack, and I soon saw that I had fractured the humerus somewhere about the middle of the bone.

There was great consternation manifested by the family when I told them the child had a fractured arm. They at once asked how it happened, and I told them that I did it. They had never heard of a case before, and of course, thought it due to great carelessness on my part. They were greatly disappointed and wondered if what I had told them of the prognosis were true. I assured them that the arm would be all right, and at the same time I was feeling quite sorry that it had happened. I would have felt much worse had this been my first case of obstetrics.

The arm was put up promptly in a piece of cardboard, fleeced lined, reaching from the axilla to the bend in the elbow, and rolled around the arm; over this was some adhesive strapping, and it was then covered by a gauze roller bandage. The arm was strapped to the body and left for 10 days. I then removed the arm from the body, but left the dressing on for the end of 2 weeks, when I removed all dressings, and simply pinned the sleeve to the clothing for a few days more. At the end of 3 weeks the child had perfect movement of the arm, and there was no deformity resulting.

I would like to say that any one may promise anxious parents that no harm will come of such an accident, if properly treated.

I think such interference of hooking the finger over the arm and delivering the arm separately is unnecessary, and may cause serious damage to the nerves of the arm, as well as produce a fracture, which at the best causes much uneasiness on the part of the patients, and would very probably result in a young doctor being dismissed from the case.

This case is presented just as it occurred, and a full discussion of such cases is sought.

TRANSMISSION OF CONTAGIOUS DISEASES BY MAIL.

BY

CHARLES FRANKLIN ADAMS, M.D.,
of Trenton, N. J.

Mrs. M., aged 38, received a letter from a young friend living 50 miles away, stating that he was suffering from the mumps. Eleven days after, her own parotid glands began to swell and she developed a parotitis on each side of her face. In trying to account for the infection, as there was none in the neighborhood, she referred to the letter, and that she remembered running the edges of the letter through her teeth according to a habit that she had.

A child, Norman D., aged 5, was taken with scarlet fever. At the end of two weeks he was dressed and playing around the room. At this time he received a letter from a cousin, aged 8, stating that he too was sick, but with the measles; the child was pleased to receive a letter and was allowed to play with it. Four days later he was taken sick again, and in a day or two developed a very severe attack of rubella.

As the child was strictly quarantined, I was credited with carrying the infection, until I discovered the letter.

ORIGINAL ARTICLES

THE BODY DEFENSES AND SYNCYTIOMA MALIGNUM.¹

BY

JOSEPH McFARLAND, M.D.,
of Philadelphia.

To an audience to whom the occasional mysterious occurrence of syncytioma malignum has been of interest since it was first observed, and by some of whom cases have been reported, it would be a supererogation to review the now wellknown morbid anatomy of the condition, and in accepting the invitation to address your society this evening, I hope to interest you in some theoretic considerations by which we may attain to a partial understanding of the strange phenomena of the disease.

It is to be understood from the start that we are to deal with purely theoretic considerations, and will attempt to build up a hypothesis to account for the development of the tumor, if such it can be called.

Life's manifestations are all mysterious, and we are still unacquainted with the forces that act and react upon the cells of our bodies. Many are hinted at in such vague expressions as "hereditary tendencies," "trophic influences," "organic influences," and at times we speak confidently of what are in reality nothing but names. We do not know what kind of stimulation is imparted to an ovule by the spermatozoon by which it is fertilized, yet its profound influence is evidenced by the inherited peculiarities of the resulting individual.

It is clear to every biologist and physiologist that every cell of the higher animals is subject to many subtle influences, and while it may not be astonishing to the morphologist that the tissues and organs of our bodies should be normally disposed, it is most astonishing to the biologist and the embryologist that such uniformity and regularity exist. What is it that determines the differentiation of the blastodermic layers? Why do the cells of these layers form groups from which organs are subsequently evolved? Why are certain of the cells set aside as reproductive elements? We do not know!

Embryology is a continuous series of surprises, and the common assertion that all of the differentiations of the developing embryo take place in consequence of inherited tendencies and cooperating forces, explains little.

But the embryo is not alone peculiar in the extraordinary behavior of its tissues. Those of the adult behave toward one another like the individuals of a well-organized social system, each attending to its own business, each maintaining its own integrity without trespassing upon, invading or disorganizing any other group. Indeed, those conditions in which the accidental invasion of one tissue by the elements of another, or in which the excessive activity of one organ occurs to the disadvantage of others, or the extinction of one organ to the disadvantage of the whole body, mark so distinct a departure from the normal as to constitute the essence of what we call disease.

Did it ever strike any one as peculiar that the epithelium of our skin, which is a tissue of active vegetative power, remains as a superficial covering of the body, and that its multiplying cells grow outward and upward to replace those removed by attrition instead of downward and inward to disorganize the subjacent tissues? What determines this relationship of epithelium to connective tissue, and why does it never overstep the boundary of its *membrana propria*? Is it not still more remarkable that in the looser and more delicate tissue of the organs, the cells maintain their definite relationship one to another, and to the *membrana propria*, instead of extend-

ing haphazard into the neighboring interstitial tissues? What determines these relationships, and why do they persist throughout life? Is it not remarkable that the chorionic villi shall extend into the decidua only far enough to bring their blood sinuses into proper coaptation to the decidual sinuses, and that this actively developing embryonal tissue shall perfect a certain development which is followed by its decline and subsequent disappearance? What determines that?

It is impossible to conceive that mechanical conditions shall determine such subtle relationships as we find between the tissue elements throughout our bodies. We are, therefore, obliged to look for some new explanation.

Physiologic chemistry seems to have the key to the situation in her hand, but we still stand upon the threshold, the door of knowledge being but ajar. According to recent discoveries, certain organs of our bodies furnish secretions by which growth is governed, yet the actual influence of these substances is vaguely understood. It seems well established that the secretions of the pituitary and thyroid bodies exert regulating influences upon nutrition, and that their deficiency or excess is followed by such abnormalities as myxedema, cretinism, and akromegaly.

The importance of less wellknown internal secretions is made evident by the removal of certain organs not supposed to be of importance to the general welfare. Such mutilations frequently transform the whole being, as, for example, in cases in which the sex glands are removed. Conditions at one time conceded to be reflex, or to be governed by the trophic or sympathetic nervous system, are now viewed from totally different standpoints, although only the foreshadowings of their real nature are known to us. The development of the mammary gland in anticipation of lactation may possibly have some connection with an internal secretion prepared by the cells of the corpus luteum, and, indeed, this very unique body, the corpus luteum, may prepare other substances whose stimulating action upon the cells of the body brings about other obscure changes characteristic of early pregnancy.

The studies of immunity that have engrossed the attention of experimental pathologists during the last 5 years, have shown a remarkably complex constitution of the blood, and an astonishing number of substances which act and interact in indemnifying the body against invasion by parasites and by its own cells.

To review briefly these discoveries, I must first remind you of the old observations of Nuttall, Buchner, and others, that normal blood-serum was not infrequently fatal in its action upon bacteria, and that some cases of immunity from infection may be explained through this poisonous—that is, defensive—action of the juices. Later it was shown that when animals were experimentally immunized against various bacteria, this ability of the blood-serum and body juices to destroy the microorganisms sometimes increased, so that bacteriolysis became a recognized, though inconstant phenomenon of immunity.

It had long been known that in the transfusion of blood the alien corpuscles introduced into the circulation speedily disappear, though their disappearance could not be satisfactorily accounted for, and it remained for Ehrlich and Morgenroth, Von Dungern, and others, to show that the disappearance of foreign corpuscles from the blood depended upon the combined action of certain factors which Ehrlich called "amboceptor" and "complement." The publication of this paper by Ehrlich and Morgenroth was the starting point of an immense amount of research and speculation, which has resulted in a fairly complete elucidation of the defense of the body through the destruction of invading cells.

The mechanism by which bacteria and other parasites are destroyed by the body juices, and by which heterogeneous blood-corpuscles and tissue cells intro-

¹ Read before the Section on Gynecology of the College of Physicians and Surgeons, March 28, 1901.

duced into the body are disposed of, is almost identical, and in all cases depends upon the combined action of solvent substances normally present in the juices, and variously known to different writers as the "alexin," "cytase," "lysin," "complement," and intermediate substances, which have been called "amboceptor," "immune body," "intermediate body," "fixateur," "desmon," and "substance sensibilisatrice."

The first substance, the so-called *lysin*, which will perhaps be the most convenient term for us to use in the speculation that is to follow, seems to be a comparatively invariable quantity; while the second, the *amboceptor*, varies according to the power of the individual to defend itself. Thus, in animals that have acquired the ability to defend themselves against invading cells of any kind, the specific amboceptor is greatly increased, while the *lysin* remains practically the same.

It is useless in our present speculation to enter into a discussion as to the specific or nonspecific nature of lysins. Their existence is a matter of demonstration, and their mode of action one easily learned by a few simple experiments. That lysins with solvent powers for certain cells of the organism, in whose body they are formed, circulate in the blood is shown by the studies of *nephrotoxin* made by Pearce.

We now pass to the consideration of certain experimental manipulations, by which animals injected with various products, elaborated in the bodies of other animals—products which may more or less seriously and injuriously affect them—defend themselves. For example, under normal conditions an animal requires what we will describe as a normal quantity of complementary substance—lysins—in its blood. But if such an animal be frequently injected with lysin-containing blood from another animal, it proceeds to antagonize or inhibit the action of the foreign lysin by producing an antagonistic substance, whose presence is capable of demonstration and which is known as an antilysin. Or, should the animal be frequently injected with serum containing an excess of amboceptors, it elaborates anti-amboceptors, by which their action may be annulled.

There is indeed, evidence to show that the introduction of almost any active foreign substance into the body, is followed by a defensive reaction of some kind, and that almost any substance normal to the body, introduced into it in excess, will bring about a reaction counteracting what damage its excessive presence might do. These reactions may be described as "general reactions," that is, reactions depending upon substances contained in the blood and tissue juices, and presumably common to all parts of the individual. But in addition to these defensive reactions are others, much less well understood, many of which are local. Such reactions probably account for the failure of growth and absorption of the grafts that have followed so many endeavors to reproduce malignant growths by the transplantation of tumor tissue from animal to animal. The mechanism of these defenses is, however, so complicated that it is difficult to say just what factors are general, and what are local of the reactions that take place. A consideration of tissue-transplantation cannot fail to impress us with the regularity with which certain results come about; a regularity which must occur in conformity with some law, the nature of which we have not yet succeeded in completely formulating.

Grafts of adult tissue, when transplanted into an abnormal environment in our own bodies, or in the bodies of the lower animals, disappear by absorption; that is to say, their cells shortly die and are dissolved or digested and disappear. In this process of absorption the leukocytes are active, but to my mind it is very doubtful whether the role of the leukocyte is as important as Metchnikoff and his followers would make it. Certain peculiar exceptions present themselves; thus Cohnheim was the first to observe that when fragments of periosteal tissue were transplanted, they were trans-

formed into thin plates of bone which remained for a considerable time, and then were absorbed. It would seem, therefore, that periosteal tissue has cells whose activity is less easily overcome than other cells, and which for a short time perform their normal function under the disadvantageous surroundings to which they sooner or later succumb.

The vegetative activity of embryonal tissues suggests that their transplantation might be followed by greater success, and it is indeed true that when fragments of embryonal cartilage are introduced into adult animals, they sometimes do grow and proliferate abundantly. But few of the embryonal tissues, however, show any such ability to accommodate themselves to the new surroundings, and like the adult tissues they nearly always die and become absorbed.

When we come to study abnormal conditions, a number of most interesting facts present themselves. Thus, the transplantation of grafts of the adult connective-tissue tumors is followed by exactly the same results as follow transplantation of the adult tissues themselves, and grafts of embryonal tumor tissues nearly always meet the same fate. All endeavors to transplant tumor grafts from man to the lower animals have met with signal failure, and all endeavors to transplant such grafts to healthy men have failed. The successful transplantation of tumor grafts to other parts of the patient's own body is a matter that might not only be predicted by the fact that the malignant tumors transplant themselves with resulting metastatic growths, but also has been repeatedly demonstrated by actual experiment.

The transplantation of tumors from animal to animal has failed except in a few cases in which the transplantations have been made from animal to animal of the same species.

We note with interest the uniform behavior of normal adult and embryonal tissue grafts, and abnormal (neoplasm) adult and embryonal tissue grafts. In cases in which the invasion of tissue has been spontaneously accomplished in the growth of the primary tumor, secondary invasion of other tissues may easily be achieved, but where no primary neoplasm exists, inoculation of the tumor is impossible. Why is it that grafts of tumor tissue may sometimes be successfully transplanted to animals of the same species as that in which the tumor originally developed, though all other transplantations fail?

To answer this question we must return to the already given brief review of our knowledge of cytolysis, and attempt to explain the varying phenomena manifested by the transplanted tissue grafts, as depending upon the presence or absence of lysogenic substances contained in the different tissues and reacting upon the other tissues.

We can surmise that there is something in the corium that inhibits the growth and development of epidermal cells, and causes the death of such of them as may through traumatic accident become implanted in it, and that through the action of this prejudicial substance we are constantly defended against their invasive activity. The fate of transplanted epithelium can be explained in this way, while the ready growth of epithelium transplanted, as in skin-grafting, continues only so long as it bears its normal relation to the surface of the body where it should normally exist.

The exact nature of such tissue antagonisms can only be speculated upon. Probably when in its normal environment and possessed of its normal nutrition, each cell prepares antagonistic substances—anticomplements, etc.—by which the activity of the solvent substances is destroyed. We conceive the gastric cells to defend themselves against the corrosive action of the gastric juice in this manner, for so soon as their health is destroyed they are attacked and digested. An implanted graft of tissue probably suffers solution for the same reason.

Let this defensive mechanism governing the relation

of tissue to tissue be modified, and a predisposition to cellular invasion becomes inevitable. One can conceive that the development of malignant tumors depends, at least in part, if not altogether, upon some such modification. Either the cells of the epithelium become able to dissolve and thus invade the adjacent tissues, or as is more probable, the adjacent tissues lose their ability to antagonize the invading epithelium. Such loss of balance may be the result of local conditions occasioned by parasites, or as seems more probable, depend upon constitutional disturbances, for though carcinoma begins as a focal lesion, the invasive power of its cells is manifested in all the tissues.

Now let us see how this theory of the development of malignant tumors may be applied to the origin of syncytioma malignum.

When we consider the phenomena attending the imbedding of the fertilized ovum, as described by Peters and others, we find that as the little egg reaches the uterus and lodges upon the thickened endometrium, known to us as the decidua, the cellular aggregation upon its surface, the *trophoblast*, exerts an eroding effect upon the epithelium, so that the surface is denuded and the ovum brought into contact with the deeper endometrial tissues. Once in the nidus thus prepared to receive it, the trophoblast develops villous extensions, over which the cellular mass spreads to form a thin layer, known to us as the *syncytium*. The villous outgrowths covered by this cellular tissue, through its cytolytic activity, continue to work their way deeper and deeper into the decidua until they reach its sinuses, and become bathed by the maternal blood. Thus, the ovum when fertilized, and new capabilities are thus imparted to it, is able to develop some substance by which it can successfully antagonize the maternal cells and bring its own tissues into contact with its future source of sustenance, the maternal blood.

When we follow the natural history of the syncytial tissue during pregnancy, we find that though the greater part of it remains in the spaces between the chorionic villi, in nearly all cases the uterine tissue is invaded to a considerable depth by its cellular prolongations. These usually soon disappear, but an examination of post-partum uteri shows that they sometimes persist for a considerable length of time, and not infrequently interfere with successful involution. When considerable sized masses remain, it is well known that they occasion hemorrhage and the formation of uterine polypi, which must be removed by surgical interference.

In certain rare cases, the depth to which they extend and the activity of their vegetation, lead to the formation of a peculiar hemorrhagic neoplasm in the wall of the uterus, which we know as *syncytioma malignum*. In more rare cases, fragments of the tissue entering the venous sinuses are transported to other viscera, in which they continue to grow in an identical manner.

In order that the ovum shall be properly imbedded, and shall be able to maintain its hold upon the maternal tissues, it is essential that its cells be able to combat whatever defensive cytolytic activities they possess, but in order that their growth shall not be excessive, it is equally essential that the maternal tissues defend themselves against excessive invasion. There must, therefore, exist between the embryonal and maternal tissues a cytolytic equilibrium, through which the variations favor the embryonal tissues during pregnancy and the maternal tissues after parturition. In this way the maternal tissues are compelled to submit to a certain invasion by the trophoblast and syncytium. So soon as the embryonal tissues lose their invading power, the maternal tissues once more assert themselves, and the presence of the embryonal tissues is resented. After the exfoliation and expulsion of the chief mass, the remnants are soon dissolved.

Variations from the normal condition may occasion various pathologic conditions. Thus, should the ovum

fail to provide the necessary cytolytic substance, it would be unable to secure an appropriate nidus, and failing properly in this, would, no doubt, be lost. Sterility might result from such a cause. Or should the cells of the embryo provide an insufficient amount of cytolytic energy, so that the appropriate arrangement of embryonal and maternal elements could not take place, abortion might be the outcome. Again should the ability of the embryonal cells be such as to enable them to accomplish successfully the embedding and yet fail to enable them to resist the antagonistic substance of the maternal tissues until the completion of gestation, miscarriage might result. Should the ova habitually fail to supply sufficient energy to meet the various requirements, habitual abortion or habitual miscarriage would be the result.

On the other hand, should the maternal tissues fail in their antagonism, we can conceive that the actively growing syncytium would invade the uterine wall with abnormal rapidity, or to an abnormal extent, so that during involution, fragments might be retained for an indefinite period, occasioning local disturbance if quiescent, or disorganization of the uterine tissues with hemorrhage (*syncytioma malignum*) if active. If the ability of the maternal tissue to resist the invasion of these cells was general instead of local, the formation of metastatic secondary masses in various parts of the body to which syncytial fragments were accidentally transplanted, would be the result.

THE NONOPERATIVE RELIEF OF EYESTRAIN FOR THE POSSIBLE CURE OF EPILEPSY AS TESTED IN 68 CASES AT THE CRAIG COLONY.

BY

WILLIAM P. SPRATLING, M.D.,

of Sonyea, N. Y.

Medical Superintendent of the Craig Colony of Epileptics,
Sonyea, N. Y.

Some oculists (Gould, Stevens, Ranney) contend that epilepsy is caused in some instances by eyestrain, the relief of which will cure the disease. The views of these writers on the subject are generally well known and need not be reviewed at this time.

I will, however, call attention to the fact that oculists differ among themselves as to the method required for the relief of eyestrain for the possible cure of epilepsy; *i. e.*, whether it shall be done by cutting the eye muscles, or whether the "imbalance" shall be overcome through the use of proper glasses.

Gould¹ is distinctly opposed to the use of the knife. He says: "That epilepsy has been caused by imbalance of the ocular muscles and cured by operation has been asserted, but this cannot be true, if, as I believe, the incoordination of the external ocular muscles is itself the result of ametropia."

Dr. George M. Gould, of Philadelphia, very kindly consented to come to the Craig Colony in August, 1902, examine and fit a sufficient number of epileptics with glasses to make a thorough test of this method of treating the disease. Dr. Arthur G. Bennett, of Buffalo, assisted Dr. Gould in the work. We selected 78 patients out of 800 for the purpose, and to show how thoroughly the test was carried out, I first quote the preliminary report of it as made and published by Drs. Gould and Bennett.²

We examined in all 78 patients, the youngest 10, the oldest 59 years of age, the majority being young or middle-aged adults. Of these 78, 2 were excluded because of organic diseases of the eyes, which rendered them useless for the purposes of the tests in view. Five more were excluded because of the impossibility, due to psychic or ocular amblyopia, of diagnosing the ametropia. This left 71 cases. Of these, 3 were excluded because the ametropia was of so low a degree that it was thought negligible. These patients needed no glasses, either for the relief of ocular conditions or of reflex results. Only about 4%, therefore, 3 out of 71 cases, seemed to us to have eyes

so near normality of optical conditions that they required no further attention.

Our tests, therefore, concern 68 cases, 35 men and 33 women. These were chosen for us by the superintendent, regardless of all conditions of epilepsy, age, etc., except that we requested that only patients be given us who were sane, and who could read.

The errors of refraction were estimated only after thorough paralysis of the accommodation by means of homatropin and cocaine. Dr. Bennett diagnosed the muscle imbalance, made the ophthalmoscopic examinations, and estimated the refractive errors objectively by means of the retinoscopic method. Dr. Gould made the subjective refraction and accommodation tests, and dictated the prescriptions. The subjective tests were in all cases those finally relied upon when the patients' answers could be trusted, and the results seemed the more accurate. Of the 68 cases there were:

- 13 cases, approximately 20%, of myopic or compound myopic astigmatism.
- 54 cases, approximately 80%, of hyperopic or compound hyperopic astigmatism.
- 33 cases, approximately 50%, of unsymmetric astigmatism.
- 15 cases, approximately 22%, with normal acuteness of vision (with correction).
- 23 cases, approximately 34%, with moderately subnormal acuteness (with correction).
- 30 cases, approximately 44%, with 20/40 vision or less (with correction).
- 3 cases only had regular, isometropic, compound astigmatism.
- 1 case only had simple regular astigmatism.
- 1 case only had simple hyperopia.
- 0 case had simple myopia.
- 9 cases were absolutely isometropic, i. e., about 77% had anisometropia.

The muscle imbalances of any high or complicating significance were unexpectedly absent. Indeed, in but one case did we think them worth consideration, so far as final correction was concerned.

The astonishing fact, and one that we think deserves most serious attention, is the enormous proportion among these patients of cases of injurious astigmatic and anisometropic defects; 67 of 68 cases had astigmatism, and it is most noteworthy that about half of the entire number of patients had unsymmetric astigmatism, a defect which almost inevitably produces the most injurious results upon cerebral and assimilative function. This terrible incidence of unsymmetric astigmatism in epileptics is, we judge, 20 or more times as great as in ordinary patients. We do not say that these high and most injurious ametropic defects caused the epilepsies of these patients. That can only be determined in the future by the careful records of seizures, to be kept and compared with those of the past. If none of the patients is cured by the relief of eyestrain, it would still not disprove the theory that in a certain number the eyestrain might have been the initial cause. And even if this should ultimately be shown an error, the duty of the State and the philanthropic to relieve these patients of the other morbid effects of these atrocious optical defects is one that to defer longer becomes the greatest cruelty. We have no hesitancy in saying that sewing or other hand work without proper glasses, with very high and irritating unsymmetric or other astigmatisms, and with anisometropia, is ruinous to health in one or several of many ways."

The 68 patients, 35 men and 33 women, began wearing glasses September 1, 1902,* and with few exceptions, continued to wear them until September 1, 1903.

A record of each seizure and its type was kept in each case by the physician in charge. Occasionally glasses were broken or destroyed as the result of an epileptic seizure, but they were replaced as soon as possible, always within a few days.

All physicians and nurses at the Colony understood that the test was of great value, and no one left a stone unturned to carry it out in the accurate and painstaking manner required.

The table of results presented shows the following:

1. The number of attacks each patient had during the 3 months prior to the use of glasses.
2. The number of attacks each patient had during the 3 months following the use of glasses.
3. The number of attacks each patient had during the 6 months following the use of glasses.
4. The number of attacks each patient had during the 12 months following the use of glasses.

By "attacks less," "increased," "decreased," or "same," we mean that this was the effect obtained apparently as the result of wearing glasses. In some

cases the difference is so small as to be hardly worth noting, as in Case 1, a female, whose attacks were noted "less." Here there were 59 during the 3 months before wearing glasses, 59 during the 3 months after, 119 during the 6 months after, and 330 during the 12 months after. If this patient had kept on having attacks at the rate of 59 in 3 months, as she had during the 3 months' period before putting on glasses, she would have had 236 during the year; but she had only 230. Consequently she was noted as having "less," a concession we make to the use of glasses without being able to say that they were responsible for this slight reduction.

In Case 2, a female had 9 attacks during the 3 months period before wearing glasses, 14 during the first quarter after putting them on, 25 during the second, and 66 during the year. Had she kept on at the rate of 9 a quarter, she would have had 36 only during the

FEMALES.

year instead of 66 as she did have. Consequently, her attacks were noted as "increased."

The chief facts of interest expressed in detail in the tables, are given in the following:

ONE ARREST IN WHICH CURE SEEMS PROBABLE.

One male patient (O. B., No. 3), who had 27 attacks between January and September, 1902, had 4 in September, 4 in October, and 4 in December, 12 in all, after he commenced wearing glasses, September 1, 1902. After January, 1903, he had no further attacks up to the date on which this was written—December 1, 1903—a period of 11 months.

His attacks were all *grand mal*, and of great severity, and were announced some time in advance by a motor aura in the form of a quick, jerking movement in one hand. After a few minutes, the hand, after being lifted higher with each movement, would be jerked straight above the head each time. As soon as the acme of this warning was reached, a similar movement commenced in the left hand, and went through the same order, the attacks appearing after both hands were simultaneously jerked above the head.

The patient lives an active, outdoor life, is robust and strong in every respect, and has had epilepsy since his seventeenth year—his present age being 38.

¹ Died at end of second month after wearing glasses.

² Had no attacks for eight months after using glasses.

³ Died at end of six months.

*The Buffalo Optical Company kindly furnished the glasses at cost, and sent an expert representative to the Colony to fit each patient accurately.

He shows a slight degree of epileptic irritability at times, but nothing in the way of permanent mental enfeeblement.

He is, or was, an excellent illustration of a "motor" epileptic—the type in which motor manifestations are marked to the exclusion of those that involve the psychic side.

The arrest in his disease now bids fair to pass into complete and lasting recovery.

FIVE PREVIOUS ARRESTS POSSIBLY SUSTAINED THROUGH THE USE OF GLASSES.

Male patient, case No. 19, and female patients, cases Nos. 9, 10, 15 and 20, had all been free from attacks for 9 months or longer when they put on glasses on September 1, 1902, with the exception of one young woman who had an attack in February, 1902, 8 months before wearing glasses. Only one of them, the one just mentioned, had an attack during the 12 months ending September 1, 1903, the glass-wearing period.

The improvement in all these cases having become definitely established through other forms of treatment

MALES.

prior to the use of glasses, it is impossible to say what measure of credit, if any, should be given to the use of the glasses in curing the disease.

The assumption that such treatment helped some, might be fair, though it is impossible of proof; and in any event, we must leave these 5 cases out of the list of those whose improvement was more palpably due to the use of glasses.

APPARENT DECREASE IN THE ATTACKS IN 11 CASES.

In 7 females and 4 males, there was a slight decrease in the number of attacks. In the majority of these, indeed, in substantially all of them, the decrease was so slight as to make it impossible to say that it was not due to the ordinary fluctuation in the frequency of such attacks and not to the influence of glasses.

A few showed improvement immediately after wearing glasses, that did not last. One patient, for instance,

¹ A way from Colony 3 months.

² A way from Colony last 2 months.

³ A way for 2 months.

⁴ Left off glasses after first month.

⁵ Died at end of 6 months.

⁶ Did not wear glasses after the sixth month.

⁷ Discharged at end of 4 months.

had 6 attacks during the 3 months prior to the use of glasses, none during the following 3 months, and 16 during the following year. Another had 59 attacks during the 3 months before, and 59 during the 3 months after the use of glasses while the total for the following year was 230.

ATTACKS INCREASED IN 33 CASES.

It seems extraordinary that those who experienced an increase in the number of their attacks should so largely outnumber those who had a decrease, but such is the case. Sixty-four percent, approximately, had more attacks in a given period after wearing glasses than before.

Among the females, case No. 2, for instance, had 9 before, 14 during the same period after, and 66 during the 12 months after; case No. 3 had none before, none during the same period after, but 3 before the end of the year; case No. 6 had 79 before, 165 during the same period after, and 346 during the following year.

With these cases, as with ones noted previously in which the attacks were less, it is impossible to say that the glasses were responsible for the increased number of seizures. Seizure variations in epilepsy are frequent and often marked. A patient may have no attacks for weeks, followed by a similar period in which he will have scores of them. Status and serial attacks, of course, always run up the total, and such attacks are liable to overtake any epileptic at any time.

As to whether the use of glasses, or the examination preliminary to their adoption, may bring on epilepsy or not, I am not prepared to say; but I have knowledge of 2 cases in which this appeared to be true, one of them occurring at the Colony, the other being related to me recently by a prominent oculist in this State.

W. B., a patient at the Craig Colony, had 13 attacks during January and February, 1901, after which they disappeared entirely and he had no more for a period of 17 months, and appeared to be on the high road to complete recovery. On August 23, 1902, when drops were put in his eyes, preliminary to examining them for glasses, he had an attack, followed on the same day by another. In September following, he had 1 attack; in October, 1; in November, 2; in December, 8; and during the next 11 months, he had 73 well-marked epileptic convulsions.

The relationship between the use of glasses (or the examination for them) and the redevelopment of the attacks in this case seems clear.

NO CHANGE IN THE ATTACKS IN 16 CASES

In 13 males and 3 females, the use of glasses made substantially no difference in the number of attacks. In any large number of epileptics, there are always some whose attacks occur with persistent regularity, irrespective of any new form of treatment. These cases may be of that type.

This interesting experiment seems to furnish additional proof, that in looking for the causes and cure of epilepsy, we must let our scientific view of its etiology be broad enough to cover more than a single organ and its abnormalities. It must include the entire body and all its parts, especially those of unstable consistency that are subjected to constant alterations and changes in composition. Added to these, there may or may not be elemental or acquired organic defects of the central nervous system, as a whole, or confined to some of its parts.

This view of the matter is the one that prevails at Sonyea and on which treatment is based with the result that 5% of the essentially chronic cases the Colony receives, are cured.

Some of these cures we regard as provisional. Freedom from epileptic attacks, in some cases, can only be obtained at the price of eternal vigilance. If the epileptically inclined individual fails to continue to profit by the lesson learned that freed him once from his disease, he is apt to become an epileptic again.

Some epileptics can be cured in 2 to 3 years and remain so; others can only be cured in 3 to 5 years or longer, and with the utmost difficulty kept so.

If it takes so long a time to cure the disease (a fact the best neurologists do not deny, while some, indeed, like Turner, go so far as to say that freedom from attacks should persist 9 years before cure may be said to exist), Gould's statement that follows seems, in one way, quite remarkable:

"I have," he says, "selected from my records only those instances in which cure has been immediate, certain and complete, and in which it has lasted for years."

Can epilepsy be cured "immediately?" We do not think so. Certain types of *convulsions*, to be sure, may be checked almost at once, but that is another matter.

We are happily coming more and more to look upon epilepsy, so far as an adequate plan of its treatment and its curability go, pretty much in the same light we now look upon tuberculosis. Epilepsy cannot be cured by one remedy, nor can it be cured in any length of time whose measure is not fixed by years. It can only be cured, as we believe today, by a *system of treatment* sufficiently long applied, and kept up to a certain extent by the patient after he has passed from the physician's care.

Who would have thought 20 to 25 years ago that any reputable physician would be able to proclaim today that tuberculosis is curable in 25% to 30% of all cases—"incipient," "advanced," and "far advanced," alike? These are the results announced from a *system of treatment* in vogue at the Adirondack Cottage Sanitarium.⁴

Who will *now* believe that the enlightenment of the next 20 to 25 years will enable us to cure 25% to 30% of all cases of epilepsy?

I have no hesitancy in declaring that if the Craig Colony could today admit one-half its patients before their disease is chronic or before it has existed more than a year, its rate of recoveries could easily be doubled or trebled. As it is now, less than 1.5% of all who enter the Colony have had epilepsy less than a year. But even under this great handicap, the system of Colony care and treatment is responsible for recovery in fully 5% of its chronic cases.

Personally, I deeply regret that the experiment so carefully and scientifically made by Drs. Gould and Bennett, did not yield better results. At the same time, it strengthened my convictions that epilepsy is not a "single prescription disease," so to speak—that the correction of the abnormalities of the eye alone is not any more likely to cure it than are surgical measures directed against the brain, from which so much was at one time hoped for, but from which we now expect so little.

ADDENDUM BY DR. GEORGE M. GOULD.*

In reference to the article which Dr. Spratling has been so courteous as to show me before publication, I would like to say:

1. I have had 6 cases in my private practice in which permanent cure of epilepsy has been effected by glasses alone. Many other cases have been reported. I know of two oculists who have similar unreported cases. About half of the 68 patients whose eyes were examined at Craig Colony had unsymmetrical astigmatism, an enormously high percentage of a defect, which, as all admit, is intensely injurious to the nervous system. These facts lead to the conclusion that eyestrain is a cause of epilepsy in at least a small proportion of cases.

2. The total patients examined 68
Number having no attacks for 3 months prior, or 3 months after, and which should have been omitted 8

Died or left off glasses 3

Same number of attacks prior and after 8

Attacks lessened in 3 months 19

Attacks increased in 3 months 30

The 19 patients whose attacks were lessened, had, during the 3 months prior to the beginning of the experiment, attacks 861

During the 3 following months 479

Showing a decrease of over 44% 382

Moreover, this lessening of the number of seizures in 3 months of 19 patients by 382 does not comport with the statement in the official report which says that "only one patient out of the 68 (should be 57) experienced any benefit in their disease while wearing glasses." I would like to ask if any therapeutic experiments, or if all combined made at the Colony, have lessened the number of seizures in 3 months in 19 patients by 382? I am astonished at such good results and never expected such high percentages of benefit from the test. Instead of "disappointing" it seems to me the reverse and shows the ocular factor of far more profound importance than I had expected. The eyestrain test has thus demonstrated that in about 33% of patients eyestrain may be a causal factor; in 19 of the test, the number of seizures was lessened by over 44%.

3. In 30 cases the attacks were, according to the table, increased:

Number of attacks prior 427

Number of attacks after 725

298

As compared with the decrease 382

Leaving to the good 84

4. But the noteworthy increases in the second and in the third three months periods—what of them? Only this, that without the omitted figures for the same periods before the experiment they have utterly no significance. It is wholly useless to include a comparison with mention only of the figures of one of the compared terms, the other not being given. The only figures given are for three months before and after the application of glasses. Moreover the influence of season is not given. The second and third three months periods occurred in the mid-winter season.

5. The columns in the tables headed "Remarks" sorely puzzle me. The copyist seems to have inserted the "remarks" by haphazard, the attacks spoken of as "same," "increased," and "less" having no significance, or a reversed one as regards the preceding figures. Several of these figures also differ from those printed and published in the official report issued last December. Of course, these three inaccuracies are entirely unintentional, but the figures will tell nothing, or the reverse of the truth, unless used with mathematic precision, and with the desire to make them reveal clear and useful lessons.

6. One of these lessons is, that if eyestrain is a causal factor in producing epilepsy, it can only cure when the eyes are frequently retested, especially in epileptics, and also when the glasses ordered are adjusted and kept adjusted by the expert oculist and optician. It is a source of great regret to me that circumstances prevented the subsequent visits which both had fully intended to make. There are a score of ways, especially in epileptic patients, in which the function of the glasses may be not only nullified, but the reflexes increased. In case of future tests of this kind the condition should be made that there should be a resident oculist. If the number of seizures in the nine months following application of glasses was really increased and unduly, over those of the nine preceding months—and we know nothing about this—it would be most natural. It is well known that wrong glasses or maladjusted ones are far more harmful than none at all. In epileptics the refraction will certainly change in a few months in a large proportion of eyes, and their glasses will more surely become maladjusted.

7. The second principal mistake that was made in arranging for the test was that no foresighted choosing of patients was made. It must not be forgotten that all

* Published after submission to Dr. Spratling and with his consent.

these patients had the severer, *grand mal*, type of the disease. It is plain that the test is absurd in cases in which the disease has been so chronic as to affect the mind or has been so long established as to be utterly hopeless of cure. Only the younger patients should have been chosen, and those with minds and nervous systems capable of responding to treatment. The large majority was not of this character, and no qualification was made by Dr. Bennett and myself as to the kinds of patients to be sent us. Above all other diseases, the cure of epilepsy consists in prevention, or at least, in halting the progress of the disease before it has become utterly unconquerable. Most of the cases under discussion were, of course, inveterate and chronic. A number of patients could not answer questions sanely. Under such conditions the success of the test becomes all the more astonishing.

8. Even when they are complete and accurate, "statistics must be made to open their mouths and talk." There is no significance of those given, as I have intimated, except for the three months following the application of glasses, but even of these the lack of any statement as to the common influence of season, the length of the course of the disease, the age of the patient, the intensity of the disease, and the other details also, make the results too vague. Every case must be individualized and the personal details and reasons for success or failure given. Above all, is it necessary to state the exact kind and degree of the refractive error. Dr. Spratling forgets that if the glasses lessened the attacks in three months in 19 cases by 382 seizures, that is important, and certainly not "disappointing"; he forgets that if (as is very doubtful), the seizures in the second and third three months were increased and because of the glasses, this instead of the absence of it, shows an ocular factor with amazing clearness. He also forgets that if, according to the rumor of one vaguely reported case, the attacks were increased by mere mydriasis, this does not warrant any conclusion as to the action of mydriasis in increasing the number of seizures at Craig Colony. The effect of mydriasis would hardly last over three months! The mydriatic we used lasts for but one day. If mydriasis does, *per se*, increase seizures, as is hinted, it admirably demonstrates an ocular factor. My suggestion to Dr. Spratling to put 100 of the younger and less injured patients under permanent mydriasis for a month was not accepted. It would not surprise me if the number of seizures would be thereby lessened by 50% or 75%. Private patients report almost always absence of headache and other reflexes while under mydriasis.

9. By individualizing the patients and examination of their errors of refraction, there appear profoundly instructive lessons. Every one of the patients who was bettered has an error of refraction, which makes an oculist or capable neurologist shudder. Nearly all I can identify had unsymmetric astigmatism, and usually with high anisometropia. The few without asymmetry of the astigmatic axes had ametropia of a terrible and tormenting variety.

Take a few examples:

1. The one whose attacks were lessened the most, I. M. He was 25 years of age and had 306 attacks during 3 months before, but only 222 the 3 months after the examination of the eyes. What nervous system could endure the following ametropia:

R. + S. 375 + C.O. 75 ax. 90°.
L. + S. 275 + C. 2.75 " 105°.

If his glasses should be misplaced $\frac{1}{8}$ of an inch he would inevitably suffer great injury.

2. What can a nervous system do with L. DeR's. error:

R. + S. 3.50 + Cyl. 5.00 ax. 105°.
L. + S. 2.00 + Cyl. 5.50 " 70°.

3. Or with that of M. G.:

R. + Sph. 2.75 + C.O. 62 ax. 20°.
L. + " 2.75 + C. 1.25 " 125°.

4. A. J. had:

R. - S. 2.00 - C.O. 62 ax. 90°.
L. - S. 0.75 - C.O. 75 " 180°.

5. E. D. had:

R. - S. 0.25 - Cyl. 1.00 ax. 15°.
L. + Cyl. 1.25 ax. 165°.

6. The case of O. B., the man cured, has an error which all European science says can produce no reflexes, and yet which is peculiarly of the worst, i.e., reversed and unsymmetric astigmatism:

R. - S. 6.50 - Cyl. 0.50 ax. 75°.
L. - S. 6.50 - " 0.75 " 180°.

10. But according to the report there was 1 cure in 57 of the patients tested. How does this compare with the officially reported cures at the Colony since its foundation? To October, 1902, there have been admitted 1,286 patients and of these, 16 had been cured by all the methods of treatment. This is 1 in 80. By the treatment of the eyes alone, 1 in 57 has been cured. Thus the ocular treatment alone has proportionally cured nearly one third more cases than all the combined methods pursued at the Colony. Except in the sense that all the methods of cure tried at the Colony are "disappointing," the results of the ocular test are scarcely to be called so. There is a story in Matthew xviii, verses 12 and 13, that might be called to Dr. Spratling's attention. It may also apply to epileptics with eyestrain.

SUMMARY.

Two mistakes were made in conducting the experiment: 1. Young patients, and those only with less injured nervous systems should have been chosen. 2. Resident or frequently visiting opticians and oculists should have been insured to make the retestings, readjustments, etc., most necessary. Despite these faults, together with incomplete statistics, etc., 19 out of 57 patients, for the only comparable terms given of 3 months, showed a reduction of the number of seizures of 382 (44%), and 1 in 57 was cured against 1 in 80 by all other methods of treatment that have been tried at the Colony. From the result of the experiment at Craig Colony I judge that the permanent residence at such institutions of an expert ophthalmologist would result in great monetary saving on the part of the State. Spectacles would certainly lessen the special disease, and the number of seizures. Even if they would not do so they would tremendously lessen headache, digestiveal troubles, etc. For mere humanity's sake they should be ordered. The habit of depreciation and ignoring the eyestrain factor is both cruel and unscientific.

"Cleveland Medical Journal."—The Cleveland Medical Journal, in its March number, announces a change in the editorship. Dr. P. Maxwell Foshay, who has formerly edited the journal in question in an able manner, has been succeeded by Dr. E. P. Carter. Hope is entertained by the medical profession of the middle west that Dr. Carter will be as successful in his labors as has been the former editor. Dr. Foshay has been one of the able young men in the State of Ohio in the furtherance of medical progress and ideals.

Summer Course at University of California.—At the next summer session of the University of California, which will be held in Berkeley for the 6 weeks beginning June 27th and ending August 6th, a number of European scientists will be on its teaching faculty. Professor Svante A. Arrhenius, the chemist of the University of Stockholm, will give in English a course of lectures on the application of physical chemistry to serumtherapy. This course will amount to 2 or possibly 3 lectures a week. Professor Arrhenius will also give a course upon the general subject of physical chemistry. Sir William Ramsay, of London, also will be a member of the summer faculty, and is now preparing a course of lectures to be published later, giving his views upon the recent developments in chemio theory, dealing with the ion and the electron and illustrated experimentally by the behavior and properties of radium. A third scientific visitor will be Professor Hugo de Vries, the botanist of the University of Amsterdam. He will deliver in English a course of lectures on natural plant breeding, giving his views on species and varieties, and their origin by means of mutations. The lectures will be illustrated by drawings and by specimens. The following will be the sequence in which he will deal with the subjects: Elementary species, constant varieties, over-sporting varieties, mutation and fluctuation. Seminars for special work will be held by all of these men in their special lines, and in all probability one large seminary will be formed in which all of them will participate.

THE PRELIMINARY REPORT OF A SERIES OF METABOLISM OBSERVATIONS MADE IN ATROPHIC ARTHRITIS, HYPERTROPHIC ARTHRITIS, OSTEITIS DEFORMANS AND THE NORMAL.

BY

JOEL E. GOLDTHWAIT, M.D.,

AND

CHARLES F. PAINTER, M.D.,

AND

ROBERT B. OSGOOD, M.D.,

of Boston, Mass.

[Concluded from page 553.]

G. I. A case of osteitis deformans :

Weight at beginning of the experiment.....140 pounds
 Weight at end of the experiment.....140 pounds
 Total amount of sugar eaten during the experiment.....182.0 gm.
 Total amount of salt eaten during the experiment..... 14.5 gm.
 Paper used after stools..... 40.44 gm.

FIRST DAY.

Breakfast.	Dinner.	Supper.
Steak..... 90.0 gm.	Consomme..... 200 cc.	Roast beef. 45.5 gm.
Potatoes..... 119.5 "	Bread..... 65.0 gm.	Potatoes..... 162.5 "
Rolls..... 80.5 "	Butter..... 18.0 "	Bread..... 80.0 "
Butter..... 20.5 "	Custard..... 140.5 "	Butter..... 21.0 "
Coffee..... 200 cc.		Cake..... 40.0 "
Charcoal..... 10.0 gm.		Tea..... 180 cc.
Acacia..... 10.0 "		
Peppermint water... 60 cc.		

SECOND DAY.

Breakfast.	Dinner.	Supper.
Beefsteak..... 97.0 gm.	Soup..... 200 cc.	Cold chicken.
Potatoes..... 97.0 "	Beef..... 60.0 gm.	Bread. Butter.
Bread..... 90.0 "	Potatoes..... 15.0 "	Cake. Tea.

Body gains.....	-4.30 gm.	+1.34 gm.	-.18 gm.	-2.05 gm.	-16.69 gm.

The phosphorus in the urine was a little low, but it was twice as high as it was in the first experiment, although there was even less in the food in the second experiment. The calcium in the urine was about the same, the magnesium twice as high as in the first experiment.

In this experiment the body lost considerable phosphorus. In the first experiment it gained considerable phosphorus. In the first experiment there was a retention of phosphorus and magnesium, and a loss of calcium. In the second experiment, on the other hand, there was a retention of calcium and a loss of phosphorus, magnesium, sulfur, and nitrogen.

As a summary, I will group the results of all the experiments together:

M. P. ATROPHIC ARTHRITIS.

In the 1 normal experiment there was a retention of magnesium and a loss of phosphorus, but from this experiment we cannot make any conclusions.

In all the cases the phosphorus in the urine was rather low, the calcium high, and the magnesium low, and in all the cases of atrophic arthritis and hypertrophic arthritis there was a loss of calcium by the body, and on the other hand, a retention of magnesium.

A comparison of the two experiments on Mary P. is of interest. In the first experiment she was suffering from atrophic arthritis. The second experiment was performed 1½ years later after she had apparently

recovered. It will be noticed that in the first experiment there was a gain of phosphorus and magnesium and a loss of calcium. In the second experiment, on the other hand, there was a loss of phosphorus and magnesium and a gain of calcium.

The metabolism in the case of Mr. I., who had osteitis deformans, does not seem to have certain abnormalities that can be noticed in the other cases. If we compare the metabolism of Mr. I. and the normal patients, on the one hand, with the other patients, excluding Mr. V., several points of interest can be noted. In the first place, the atrophic patients all show a loss of calcium. More calcium, .89, 1.4, 1.8, and 2.5 gm. more respectively, is excreted in the urine and feces than is taken in the food. In the normal patients, in one case we have neither gain nor loss, in the other gains of ½ gm., 1.3 gm., respectively.

Voit,¹⁶ Tereg and Lehmann,¹⁷ Miller,¹⁸ Forster,¹⁹ Hoppe-Seyler,²⁰ and Rey,²¹ have shown that calcium is excreted in large part into the intestines. Our figures show that the excretion of calcium into the intestines is increased. In the normal cases 65%, 67%, and 78%, respectively, of the amount of calcium taken in the food is found in the feces. In the rheumatoid cases, respectively, 89%, 90%, 95%, and 97% as much CaO as there was in the food was found in the feces.

After feeding of calcium salts, decreased excretion of P₂O₅ in the urine has been found by Schetelig,²² Lehmann,²³ Tereg and Lehmann,¹⁷ Haubner,⁴ Riesell,⁵ Bertram,⁶ and v. Noorden.⁷ The phosphorus in this case seems to be carried into the feces. In our atrophic cases we should expect that the addition of calcium from the tissues to the excretory products would act like administration of calcium salts in this respect, and, in fact, this is so. We should expect a decreased excretion of P₂O₅ in the urine, an increase in the ratio $\frac{P_2O_5 \text{ in feces}}{P_2O_5 \text{ in urine}}$, and a decrease in the ratio $\frac{P_2O_5 \text{ in the urine}}{P_2O_5 \text{ in the food}}$.

In the atrophic cases, we have an average of about .85, .9, and .9 gm. P₂O₅ per day, respectively, in the urine. In the normal cases the figures are, respectively, about 1.5, 1.8, and 2.1 gm. P₂O₅ per day.

The ratio $\frac{P_2O_5 \text{ in urine}}{P_2O_5 \text{ in feces}}$ is about 1.34 : 1, 2½ : 1, and 1¼ : 1 in the normal case. In the atrophic cases, the ratio is about ¼-1, ⅔-1, 1⅓-1, and 1-1, respectively. That is to say, whereas normally there is about twice as much P₂O₅ in the urine as in the feces, and in the atrophic cases we have no more P₂O₅ in the urine than in the feces.

Again, in the normal cases, we have respectively, about ⅔, ⅔, and ⅔ as much P₂O₅ in the urine as in the food. In the atrophic cases only about ⅓, ⅓, ⅓, ⅓ as much P₂O₅ is found in the urine as in the food.

All the facts point to a loss of calcium from the body tissues in the atrophic cases. This calcium is excreted into the feces and carries P₂O₅ with it.

According to Heiss,²⁴ the muscles contain about twice as much MgO as CaO, and the blood 6 times as much. The bones, on the other hand, contain 60 times as much CaO as MgO. In view of the fact that the bones contain so much CaO, the abnormal metabolism CaO in these bone diseases is not so very surprising. The MgO does not seem to show such striking change.

NERVOUS COMPLICATIONS OF TYPHOID FEVER.*

BY

HERBERT A. BLACK, M.D.,

of Pueblo, Colo.

Typhoid fever is no longer considered a disease of the small intestine alone, but one of general infection, in which all tissues of the body are more or less affected. The osseous, muscular, glandular, liquid, and nervous tissues, have in turn at some time borne the brunt of an attack, not only from the toxins but from the bacilli themselves, which have been found in nearly every organ of the body. It is not even necessary that we should have intestinal lesions to maintain our diagnosis of typhoid fever, for the primary foci may be entirely removed from the small intestine. There are recorded in medical literature many cases which clinically presented true pictures of typhoid, yet an autopsy revealed no lesion of the intestines whatever.

Lautigan¹ reports the case of a man of 35, who had the usual symptoms of the disease, with some vomiting, constipation, and delirium toward the end of his illness. At postmortem the intestinal mucous membrane, Peyer's patches, and solitary glands were found perfectly healthy; the liver was enlarged, and its cells had undergone cloudy swelling; the spleen and retroperitoneal glands were also enlarged, and sections of the mesenteric glands, liver, kidneys, and spleen showed bacilli resembling the bacilli of Eberth, while in cultures from the heart, blood, lung, liver, spleen, and gallbladder the typhoid bacilli were present in pure culture. Thus the microscope has shown that the extra intestinal symptoms are not due to bowel lesion alone, but to bacilli, as well as toxins, far removed.

From early record this fever has been recognized as having associated with it distinct nerve lesions, as is shown by the term "nervous fever," given by Gilchrist in 1734, and "meningo gastric," given by Pinel, 1798, but before considering in detail the nervous complications of typhoid fever, permit me to quote you an extract from a most interesting paper by Foulerton and Thompson,² on "Causation of Nervous Symptoms in Typhoid Fever": Two cases of marked cerebral irritation which came to autopsy were examined bacteriologically. The first patient had marked cerebral symptoms, but none that pointed to definite meningeal inflammation. Autopsy showed brain and membranes normal, and culture from surface of the brain and cavities of lateral ventricles gave no bacterial growth. The second patient suffered convulsive twitching, retraction of the head, facial paralysis, and slight oscillatory movements of the eyes. Upon autopsy there was found injection of the pia mater, and in the lateral ventricle an excess of reddish-brown fluid in which were found the bacillus of Eberth and *Bacillus coli communis*. Section from the cerebral cortex in these cases revealed in the first no pathologic change, while in the second the outlines of some of the cell bodies were indistinct, and some of the cells much swollen. In a few of the cells the Nissl bodies had disappeared, leaving small unstained areas. Nichols³ reports his conclusions, obtained partly from 3 cases of human typhoid, and partly from animals dying of typhoid infection, as follows:

That in typhoid fever the motor cells of the spinal cord and the nerve cells of the dorsal root ganglions regularly suffer pathologic change in the course of the

infection, though the alteration in the motor cells is more constant and intense than that in the cells of the sensory ganglia. The changes are identical with those found in most animals after section, destruction or injury of the peripheral nerves. From his findings in the sciatic nerve with infection experimentally induced, he believes that posttyphoid hyperesthesia and paralysis are due to lesions of the peripheral nerves.

The pathologic findings which have been recorded appear to establish the fact that nervous symptoms may be due either to the toxin or the typhoid bacilli, while the pathologic changes in the nerve tissues are more frequently due to the direct action of the bacilli. Leaving the pathology, I will now consider the various nervous symptoms encountered in this disease.

Cephalalgia.—No one symptom is more commonly present in typhoid fever than headache. Stewart,⁴ in a report of 620 cases, gives it as present in 93% others have found it as high as 96%. In my own cases I have found it is 94%. It may vary in degree from a slight frontal pain lasting only a few days to a severe frontooccipital headache of such intensity as to cause suspicion of meningitis, which may last during the greater part of the fever, though it usually subsides with the full development of the disease. The pain is usually more severe in the afternoon and early evening, although it may be either continuous or neuralgic in character.

Convulsions are a rare complication of the disease, although as we would naturally expect, more commonly encountered in children than in adults. Clayton⁵ reports 3 cases occurring between the twenty-seventh and thirty-fourth day of the disease, and attributes them to the intense action of the toxins upon the exhausted nerve centers, but convulsions may follow thrombosis of the veins or arteries of the brain. Convulsions may be due to nephritis, as Murchison reports this condition as obtaining in 1 out of the 6 cases he had observed.

Delirium is one of the most frequently encountered nervous symptoms in typhoid fever. It may exist before any elevation of temperature, as is shown by Dieters⁶ in his report of 2 cases in which there was maniacal delirium, in 1 case for 2 days and another 3 weeks before fever appeared, but usually the condition obtains about the second week and ceases during convalescence, although it may last after defervescence. The severity and type vary in different cases, more often it comes gradually, appearing especially at night and may at first amount to only slight confusion of thought or incoherence of speech, this increasing to a low-grade muttering delirium which may deepen to coma. When early in development, it is more apt to be active and maniacal in character, though it may show that tendency at any time. Usually the more active the delirium the more grave the danger, and we may get all the various forms of delirium in a single case. Rarely has there developed a suicidal mania. In many cases in which delirium is not present the patient will answer questions rather incoherently when no other mental aberration is noticeable. In such cases we find that upon recovery the patients remember dimly, if at all, anything which occurred during their illness. Since the more general use of cold applications in the treatment of typhoid fever, the mental conditions of our typhoid patients have been clearer and when delirium is present it is more mild than formerly.

Meningitis.—No complication of typhoid seems to have more doubt, and probably correctly, cast upon it, in respect to the accuracy of diagnosis than that of meningitis, for the symptoms given are probably produced by the action of the toxins on the nerve cells and not, in most cases, by a true inflammation of the meninges. The diagnosis of meningitis in a disease so constantly characterized by functional cerebral derangement is complicated with much to confuse the attending physician. Of 15 cases reported by Keen⁴ were first diagnosed postmortem. He also states that he believes many cases

* Read before the Pueblo County Medical Society, December 1, 1903.

are overlooked and symptoms of acute inflammation are masked by general stupor and supposed to be only a part of the typhoid delirium.

I have a case to report in this connection.

D. W., aged 25, American. Personal and family history good. About October 10, he began to lose appetite; malaise, and later slight diarrhea and afternoon headaches appeared. He worked until October 17, when I was called and found his temperature 103.3°, pulse 98. On pressure there was slight tenderness and gurgling over the ileocecal region; there was no tympany, tongue was coated, muscular pain was general. The patient complained of chilly sensations and at times would have marked rigor. Temperature remained about the same, although in spite of the ice-caps the headaches increased gradually. Active delirium was noticed during the night of October 20, subsiding on the following morning, only to recur again at night; this symptom increased until October 24, when the patient was delirious the entire time and required the constant attendance of a nurse to keep him in bed. On October 26, photophobia and retraction and rigidity of the cervical muscles were noted, followed by strabismus and intense injection of the conjunctiva of both eyes. October 28 deafness, due to otitis media, of the left ear became apparent and from then on till November 10, a foul discharge was present. From October 27, tremor was markedly noticeable together with frequent clonic spasms of the extremities. One feature of restlessness was a to-and-fro motion of the right forearm at right angles to the arm, which was maintained incessantly for 5 days and nights. The initial diarrhea was followed by slight constipation about the beginning of the meningeal symptoms but soon reasserted itself and from that time to November 6, there were involuntary passages from the bowels and bladder. On October 29, Dr. Work saw the case in consultation and diagnosed meningitis complicating typhoid. Prognosis, we both felt, was grave. Temperature ranged without rhythm from 100° to 103.1° per rectum. The pulse, which owing to restlessness could not be taken with regularity, ran from 110 to 142 beats per minute. On November 7, the disease appeared to reach its height and from then there was a gradual improvement until December 2, when the temperature remained normal all day. The recovery was complete except for deafness in the left ear, which later improved under treatment.

In this case I realize that the diagnosis of typhoid-meningitis is open to criticism, as no bacteriologic test was made of the cerebrospinal fluid, but against that, the symptoms scarcely admit of anything else, and as cerebral symptoms developed prior to the occurrence of the otitis media, I believe we should exclude it as a cause of the meningeal inflammation.

Keen found recorded since 1876, 15 cases of meningitis complicating typhoid fever, in 12 the bacilli were obtained in pure culture. In the literature of the past 5 years I find record of 6 cases in which Eberth bacilli were alone found. While the records of this complication are few, yet its existence is proved, and every case with cerebral symptoms should be carefully watched for its possible occurrence.

Cerebral Abscess.—McClintock⁷ found recorded, 5 cases, his own making the sixth, of cerebral abscess following typhoid fever, although in only one was there proof of its being due to typhoid bacilli.

Hemiplegia and aphasia are rare complications of typhoid, yet medical literature makes mention of some 20 cases, the majority of which occurred during convalescence or after the disease had reached its height. The only case I have ever seen occurred in my practice last year; the history is as follows:

A. R., aged 21, American, personal and family history negative. I first saw the patient on November 7, at which time he gave a history of about 10 days malaise, loss of appetite, very slight headache. His temperature was 101° in the evening, pulse 100. Intestinal symptoms were slight; later rose spots, and distinctive although mild bowel signs developed; fever ranged from 99.3° to 101.4°; pulse, 96 to 116. Examination of the heart revealed evidences of a mild endocarditis. The fever ran a low grade type, and all evidence pointed to a rapid convalescence until November 24, when I was hastily summoned about 6 a.m. Upon my arrival I found the patient was pale, face had an anxious expression, skin cold and moist, pulse very rapid and weak, temperature subnormal, intense lateral nystagmus, especially of the right eye, partial aphasia and complete hemiplegia of left side. The following day the active nervous symptoms were less marked, but hemiplegia was complete together with anesthesia. Dr. Work was called in consultation, and concurred in diagnosis of embolism lodged in right middle cerebral artery. On November 26, the right eye was found most completely injected and sensitive to the light,

temperature was 102° and rose to 103.1° in the next 2 days. From this time all symptoms improved, though very slowly, to February 20, 1903, when the last record was had of rise of temperature. The hemiplegia and anesthesia had improved, but had not entirely cleared away, and there was slight ptosis of eyelid when last heard of in November.

This case I believe (if my diagnosis of endocarditis was correct) one of embolism from the heart lesion, which in turn was induced by typhoid infection, or it may be that the cardiac murmur was only that commonly encountered in this disease, for after the patient was able to be up and about, no heart lesion was discernible. Had the typhoid infection been more severe we might have looked upon this condition as a result of dyscrasia, but with the mild symptoms presented it would hardly be probable in this case. Annequin⁸ reports a somewhat similar case with paresis of the left side of the body.

Neuritis occurs in a small number of cases. The most common form is probably the condition referred to by Osler and Hanford as "tender toes," when the tips and pads of the toes become extremely sensitive, so that the slightest touch causes pain, even the bed clothes causing unbearable suffering, which was the condition in the meningotyphoid case above referred to; this condition of the toes is not accompanied by any wasting or distinct loss of sensation. White⁹ reports a case of localized neuritis occurring about the commencement of convalescence. Pain of a sharp shooting character first appeared on the inner side of each elbow, radiated along the ulnar side of the forearms and extended to the ulnar side of the ring fingers; the fingers became stiff and useless, with atrophy of the interosseous muscles; there was inability to extend the fingers completely, strong flexion of the little finger, adduction of the thumb and anesthesia of the ulnar side of the hand, both sides of the little finger and ulnar side of the ring finger, the left hand being somewhat less affected than the right. Spiller¹⁰ refers to the report of 17 isolated ulnar paralyses following typhoid, collected by Liepelt (of 12 of which he made special study.) In 9 of these the paralysis began in convalescence, pain was an early symptom in 8 cases, and atrophy was present in 9 of the cases. In local neuritis there seem to be marked atrophy, affecting chiefly the extensor muscles, and more or less complete paralysis, together with degenerative change.

Paralysis in many forms other than those mentioned is encountered during or after an attack of typhoid fever. It may be due to degenerative neuritis or to a central lesion in the brain or spinal cord; acute anterior poliomyelitis, Landry's paralysis, acute ataxia, oculomotor palsy, and paralysis of the palate have each occasionally been carefully reported in medical literature, and in this connection with the more rare forms of typhoidal paralysis, I wish to mention a case which came under my care last December.

R. J., aged 17, an overworked, poorly nourished boy, whom I was called to see on December 4. I found the usual symptoms of beginning typhoid fever, but rather more catarrhal laryngitis than is usually present. Temperature during the attack ran from 101.3° to 104°; pulse was typical. Diarrhea was a little troublesome. On December 24, and again on the following night, the patient had difficulty in breathing, which his mother described as "croup." No ulceration of the larynx was to be found, mucous membrane was congested, and the voice had some laryngeal stridor noticeable the following morning. Fever disappeared on December 29, and the patient was apparently making a typical convalescence when I discharged the case on January 5. Previous to this, however, I prescribed strychnin and iron for an anemic condition, which had been present during the illness. On January 16 I was called; I had not heard from the patient since January 5; I found him sitting in a chair gasping for breath; face was waxy and of marble whiteness, eyes sunken, pulse rapid, breathing markedly embarrassed, total loss of voice, no cough and stridor only on deep inspiration. I called Dr. Bulette in consultation, and upon examination he found the mucous membrane of pharynx and larynx bloodless; a view of the trachea presented a like appearance; total bilateral paralysis of the abductor muscles of vocal cords was present. The patient had been unable to take food for 2 days previous, on account of choking when attempting to swallow; the family said he had been gaining until a week previous when the symptoms noted first appeared; electricity

and large doses of strychnin were administered, but without the slightest benefit, the patient dying 2 days later.

This case was evidently one of paralysis of the laryngeal branches of the pneumogastric nerve, but whether from posttyphoid neuritis or from a central lesion is a question I have never been able to answer to my own satisfaction, as an autopsy was not obtainable.

Among other posttyphoid nerve sequels is the so-called "typhoid spine," described by Gibney as an acute inflammation of the periosteum and fibrous structure, but which Osler believes to be a neurosis. Another rare sequel is insanity developing after a typhoid attack, a typical case of which is described by Farrar.¹¹

A woman of 41 developed after the fever an acute maniacal condition which with the typhoid attack extended over a period of 1 year, 6 months of which was spent in a hospital for the insane. Her condition improved, but was never so good after this illness as previously, and intermittent hysteric phenomena have been present during the 8 years following the posttyphoid mania.

There is hardly a nerve symptom which may not be present with or follow an attack of typhoid, and surely no set of symptoms present greater interest in connection with the disease than do those affecting the delicate nerve structures.

CHOLECYSTECTOMY VS. CHOLECYSTOSTOMY. A PLEA FOR THE PLAINTIFF.¹

BY

MAURICE KAHN, M.D.,
of Denver, Colo.

Surgeon to the Emergency Hospital, Alternate Surgeon to St. Anthony's Hospital.

Hutchinson recently stated that the gallbladder is a nearly functionless organ, insufficiently capacious to act as a reservoir of any value, and inadequate in muscular power to exercise any important effect upon the pressure of the bile flow. It is chiefly noteworthy as a settling basin for stone formation, and as a suitable harbor for the multiplication of pathogenic bacteria. In short, it seems a source of danger greatly disproportionate to any usefulness which it may possess.

That it is not needful to health has been proved on innumerable occasions by its removal without noticeable injury. That its removal is essential to comfort in many cases is an indisputable fact.

Not long ago, Roswell Park directed attention to the many characteristics of the gallbladder analogous to the appendix, and advocated like treatment of this viscus when diseased, as would be afforded the appendix under similar conditions. The earlier writers on surgery of the biliary tract advocated cholecystostomy and drainage to permit the spontaneous discharge of stones frequently overlooked. While this was sufficient in Tait's day, it is insufficient now except, perhaps, for those few, found in every age who, recreant to their trust, remain stoically apathetic to the penetrating light of advancing science.

In the past, stones situated in the common duct were the ones most frequently overlooked, but at the present time, by practising the Robson technic, with which exposure of the common duct, even in obese subjects is accomplished with comparative facility, with patience and care such an event should not often occur. Further-

more, as impacted stones in the common duct usually result in a dilation of the ducts, digital exploration is frequently possible. Notice was first called to this by Mayo Robson, who strongly emphasized the point.

That cholecystectomy is not more hazardous than cholecystostomy is a fact substantiated by every surgeon of experience with the 2 operations. It may be said here that septic cholecystitis is no more a counterindication to cholecystectomy than septic appendicitis is a counterindication to appendicectomy. Further, the thick-walled bladders found in pus cases are functionally useless anyway, and should be excised to avoid the peril of a second operation.

Any operation on the gallbladder presupposes some disease thereof, if for cholelithiasis, then the presence of these stones, in accordance with modern pathology, is evidence of a diseased gallbladder, and as a diseased gallbladder is a menace to life, it should be removed, and not merely opened and drained. For weeks, and sometimes months, following cholecystostomy, there is a troublesome fistula discharging irritating secretion. The fistula may be persistent, necessitating secondary cholecystenterostomy or cholecystectomy. A grave toxemia consequent upon cholecyst disease is not uncommonly encountered. Drainage would afford temporary relief perhaps, but without any assurance of its permanency. Pancreatitis may be coexistent. Ablation of the gallbladder eliminates the risk of its aggravation from disease of this organ, and there will not be any stones subsequently to irritate the pancreas. By excluding the probability of stone formation we practically eliminate the possibility of cancer from this cause which is universally conceded to be by far the most frequent etiologic factor. Succeeding empyema is impossible as is also secondary obstruction of the cystic duct with its periodic colic, proceeding from gallbladder secretions being forced through the strictured duct, which stricture follows ulceration of the duct or kinking or constriction from adhesions. Again, postoperative adhesions are more extensive in cholecystostomy than in cholecystectomy, hence a greater likelihood of their limiting the normal movements of adjacent viscera particularly the stomach and duodenum, possibly demanding secondary operation for their release. Besides, in drainage cases there is greater danger of hernia developing.

In cases of impacted stone in the cystic duct, the trouble of its removal is avoided and time saved by ligating below the stone and removing duct, bladder and stone entire. Also, as stones in this situation have frequently escaped observation, this danger would also be avoided by its complete removal.

Mayo's method of removing the gallbladder, I consider the simplest. Briefly, it is as follows: The cystic duct is cut across, above curved forceps which clamp the duct and vessels. The duct and bladder are then removed from below upward, thus avoiding the troublesome hemorrhage with obscuring of the operating field which occurs in working from above downward when the same vessels are severed again and again.

As evidence of my robust faith in the procedure advocated, it will be sufficient to report a case in which operation was done some time ago. It is noteworthy that the case presented the two conditions which typify the classes wherein drainage is usually advised, viz., stones in the common duct and empyema.

I was summoned on the evening of December 24, 1902, to attend Mrs. G., aged 23. The patient had been married 2½ years and had 1 child, 2 months old, nursing. A miscarriage occurred 1½ years ago. Present illness began in July, 1900, since which time she has had occasional attacks similar to the one for the relief of which I was called, but less severe. She complained of excruciating pain in the epigastrium and right hypochondrium, and cried lustily for relief. Pain during the attack, extended up posteriorly to between the scapulas.

Examination showed a well-developed and well-nourished woman, slightly jaundiced; right rectus muscular rigid; epigastric and right hypochondriac regions sensitive, as was also a small area posteriorly about the eleventh dorsal vertebra;

¹ Read before the Colorado State Medical Society at its thirty-third annual meeting, held at Denver, Colo., October 6, 7, 8, 1903.

slight dullness over the area of the gallbladder; no nausea nor vomiting; no history of chill; perspiring some at time of visit. Temperature 99.6°; pulse 100.

The diagnosis of gallstones was made and operation advised. Periodic pain continuing, consent to operation was obtained December 29.

Operation December 30: A longitudinal incision of 3½ inches was made through the right rectus muscle, separating its fibers. After opening the peritoneum an exploring finger found the intestines adherent to the anterior abdominal wall.

The gallbladder was buried in adhesions, involving the stomach, small intestines, and colon. The gallbladder was liberated with great difficulty; profuse oozing was a bothersome accompaniment, particularly in breaking up some of the more recent adhesions. As is not infrequently the case, the tissues were so friable that the ligature could not be utilized for the control of hemorrhage. After walling off the thickened and distended gallbladder, it was incised and emptied of pus; 130 stones were also removed, many of which were packed in the common and cystic ducts. Some of these were extracted with forceps; some were extruded by a process of milking, with pressure from without the ducts. Following this, the gallbladder and its duct were removed *in toto* by transfixing the stump, tying in two directions, and cauterizing with carbolic. The friability of the surrounding tissues would not permit of the stump being overspread. By reason of the peritoneum being so easily lacerated, the abdominal wall was closed in two layers instead of the usual three. Patient left the table with pulse of 120. The wall of the gallbladder measured a quarter inch in thickness. She made an uneventful recovery. The wound healed kindly by first intention, and the patient was on the street on the fourteenth day following the operation without a postoperative abdominal belt.

It is remarkable that the patient was treated for 2½ years by numerous physicians for "stomach trouble." The age of the patient was doubtless a factor in the erroneous diagnosis. Be this as it may, I believe such errors are of too frequent occurrence, and should be carefully guarded against by the intelligent interpretation of the symptoms evidenced rather than by the search for a certain index or a pathognomonic sign.

CORNEAL ULCERATION DUE TO NASAL INFECTION.*

BY

S. LEWIS ZIEGLER, M.D.,
of Philadelphia.

Attending Surgeon, Wills Eye Hospital; Ophthalmic Surgeon, St. Joseph's Hospital, Philadelphia.

The microorganisms generated in the nasal cavities and accessory sinuses of the head have been gradually assuming their proper importance as pathogenic factors in ocular disease for more than a decade past. Ziem,¹ in his admirable monograph, states his belief that "two-thirds of all cases of ocular disease arise from nasal disturbances." In a paper presented some 9 years ago, the writer² made the following statement: "I think we may safely say that fully 90% of corneal lesions take their origin directly from preexistent pathologic processes affecting the intranasal tissues and secretions. Careful inspection will almost invariably reveal associated lesions of the eye and nostril of the same side, which is most markedly shown where the disturbance is confined to a single eye and the corresponding nostril."

There are 3 different avenues for the transmission of disease from the nose to the eye: (1) By the lacrimo-nasal duct; (2) by the blood and lymph streams, and (3) by reflex action through the nervous system. Although bacterial invasion has been traced through the blood and lymphatic circulation, we will only consider their transmission through the lacrimo-nasal canal.

In order to limit our discussion still further, we will confine our attention to *ulcerative* lesions of the cornea.

The cornea is probably the most vulnerable tissue of the eye, owing to its anterior location and its consequent exposure to traumatism and infection. Any inflammation of the corneal substance may so affect its transparency that vision may be partially impaired or even lost,

especially when the resulting opacity is centrally located. Such lesions should, therefore, receive early recognition, and have efficient treatment promptly applied in order that any disturbance of the visual acuity may be prevented.

For our present purposes corneal ulceration may be subdivided into 3 varieties—the simple, the phlyctenular, and the sloughing.

Simple corneal ulcer appears as a small gray or grayish-white lesion of the corneal surface, accompanied by pericorneal injection. Phlyctenular ulceration manifests itself as a pustule or vesicle, to which is attached a narrow leash of bloodvessels. Either of these varieties may become suppurative in character, or even result in perforation of the cornea, if proper treatment is not promptly instituted.

Accompanying these local symptoms is a characteristic clinical picture that cannot fail to indicate the diagnosis. There is intense photophobia, which the child attempts to alleviate by burying its head in a pillow or in the folds of its mother's dress. There is marked blepharospasm, the lids being gripped together so tightly that it is almost impossible to open them. Lacrimation is often excessive, and occasionally a mucopurulent discharge is present. The nasal secretions are viscid, acrid and irritating, often hanging down on the lip and causing eczematous excoriation. Occasionally the face is covered with an acneous eruption, and the skin of the whole body appears ashy-pale, relaxed and leaky, being bathed in perspiration, while the hair is matted together by the excessive moisture present. In cold weather the perspiration and chilliness of the body surface leads to excessive zeal in overdressing, which only adds to the existing trouble.

Sloughing ulcer usually arises in 2 ways: 1. From some small wound of the cornea, which is either infected by some germ deposit carried on the foreign body itself, or more frequently by the excessive bacterial growth occurring in the tear duct. 2. It may also occur in the course of the exanthems or other fevers; (a) by infection with excessively virulent bacteria following maceration and lesion of the corneal surface through acrid secretions, and (b) by actual local pustulation. The rapid breakdown of the cornea, the wide extent of the ulceration, the mucopurulent discharge and the extreme physical prostration of the patient will promptly indicate the more serious character of this lesion.

The pyogenic germs may penetrate the corneal layers before there is actual perforation, and cause what is termed hypopyon, or pus in the anterior chamber. In the simple or phlyctenular ulcer this material will be promptly reabsorbed; but in the sloughing variety a more serious infection may result.

The nasal etiology of these corneal lesions involves many factors. The inspired air carries into the vestibular air chambers innumerable spores, many of which are retained and undergo fermentation, because of the essential elements of heat and moisture present. The accessory cavities furnish in still greater degree these fermentative possibilities. If, then, their mucus contents become infected by these invading organisms, almost unlimited multiplication will occur. So long as the secretions can escape freely the bacteria are washed out by the flux. When, however, partial or complete occlusion of the sinus orifice occurs, a veritable bacterial pest-house or breeding-ground for germs is thereby established.

The accessory cavity that is chiefly involved in these processes is the maxillary sinus or antrum of Highmore. Its location, its ease of obstruction, and its anatomic conformation as a pear-shaped sac with a superior opening (thereby permitting retention of all fluids except the overflow), all tend to make this cavity what is practically a semiclosed cess-pool filled with the pathologic products of decomposition and fermentation. We must agree with Bosworth³ when he says, that "it is an invariable rule

* Read before the New Jersey State Medical Society, June 24, 1903.

that a catarrhal secretion in a closed cavity must give rise, sooner or later, to a purulent discharge."

The mucous membrane composing the orifice and canal, which is the means of exit from the antrum, is oftentimes tortuous in its passage through the bone; it may be loosely adherent and thrown up in folds; it may be unusually susceptible to vascular dilation and engorgement; or it may be easily irritated by the outflow of acrid secretions. Atmospheric humidity and low barometric pressure may cause venous stasis. Hyperesthesia of the Schneiderian membrane; the irritation set up by contact of the intranasal mucous surfaces themselves; the local irritation of particles inhaled in breathing; the influence of heat and cold, either local or systemic—one or all of these conditions present will quickly demonstrate how easily this small canal may become partially or wholly occluded, thus shutting off the antral cavity.

The mucous membrane lining the antrum is likewise subject to certain pathologic changes. There may be simple hyperemia with hypersecretion due to chilling of the surface of the body. If this chilling suddenly checks perspiration, the normal amount of urea excreted by the mucous membrane of the antrum is considerably augmented by the vicarious action which it assumes in order to help eliminate the excess of urea in the system. The congestion and closure of the antral orifice creates, therefore, what is practically a cyst or bladder, and we have set up by means of the bacterium urea, a pathologic process which is a pure analog of cystitis as it occurs in the urinary bladder, and which will run a similar course. The urea, through a biochemic action, changes into ammonium or ammonium carbonate, both of which are intensely irritating to the mucous lining of the cavity, and at the same time the excessive alkalinity coagulates the mucus contained therein. The fluid serum continues to be secreted, and thus the coagulated mucus rises to the upper portion of the chamber, and because so coagulated is extruded into the nasal cavity with difficulty.

If now we concede an infectious cystitis of the antrum, we can comprehend how it is possible for an unlimited stream of pathogenic microorganisms to be poured out onto the cup-like floor of the nasal chamber, and by capillary attraction drawn up into the lacrimo-nasal duct, and thence to the ocular culdesac.

The lacrimo-nasal duct itself is, moreover, a most fertile nidus for this bacterial development. The presence of strictures, viscid secretions, ulceration of the lining membrane, or interstitial thickening of the same, all tend to interfere with its syphonic action in the downward drainage of the tears. The bacterial growth is greatly facilitated by the consequent stagnation. Not only are the tears prevented from passing into the nose, but microbial infection is carried upward to the eye by the regurgitation of these septic secretions.

Whether the actual break in the corneal epithelium is due to the maceration caused by this acrid alkaline fluid, or whether there is a direct erosion due to adhesion of the bacterial colony, is immaterial. We believe that both pathologic processes are possible. Of course corneal abrasion by direct traumatism is always a possibility. The friction of rough granular lids may thus become a causative factor.

The microorganisms that have been most frequently found in these conditions are the pneumococcus, the staphylococcus, and the Klebs-Löffler bacillus, while the streptococcus and the gonococcus of Neisser are more infrequent factors of infection.

We must not overlook the fact that there is a constitutional element in the disturbance—chronic constipation, errors in diet, poor food, and unhygienic habits are important factors to be considered. Nasal obstruction and mouth-breathing are especially deleterious, because orally inspired air cannot evaporate intranasal fluids, and because lowered oxidation and metabolism almost invariably result.

In children the exanthems are immediately or remotely responsible for many of these conditions, while teething is often a causative agent. In hospital work, however, I have found the most unvarying genetic factor to be *over-indulgence in coffee, tea and sweets*. They sap the vitality and create a peculiar gastrointestinal irritability that is hard to overcome, and which reflexly adds to the nasal disturbance. When taken in excess they overload with xanthin compounds an already weakened system, and, like alcoholic excesses, inhibit proper elimination of the system's waste, thus resulting in what is practically katabolic stasis.

Having thus briefly reviewed the etiology of this disease, we may properly characterize corneal ulcer as a purely local inflammatory process, arising chiefly from infection by septic lacrimo-nasal secretions, and frequently complicated by lowered oxidation and metabolism.

TREATMENT.

The Nose.—The nasal origin of this affection indicates the treatment to be applied. Irrigation of the nasal chambers with an antiseptic or saline solution should be carefully carried out. If pus is present, hydrogen dioxid (diluted 1 to 4) should be dropped into the nostril by the ordinary eye-dropper, 2 or 3 times a day, and allowed to trickle back into the throat.

Local applications for the reduction of the turgescent membranes are often necessary. A weak solution of cocain (1% to 2%) may be applied with cotton wrapped on a wire applicator. This may be followed by an application of

Camphor	} of each65 gm. (10 gr.)
Menthol		
Tr. benzoin comp.	7.5	cc. (2 fl. dr.)
Boroglycerin (50%) . . .	q.s. ad. 30	cc. (1 fl. oz.)

Apply to nose daily, or on alternate days.

If any more serious nasopharyngeal lesion is present the patient should be promptly referred to the rhinologist for relief. Enlarged tonsils or adenoid vegetations in the pharynx, and septal spurs, polypus or other nasal growths should have surgical attention. If the ocular condition has become chronic it may be necessary to reduce the hypertrophied and turgescent turbinates by galvanocauterization. The object to be accomplished by such a procedure is threefold—to promote free antral drainage, to secure freedom from pressure contact, and to obtain free nasal breathing.

The Tear Duct.—The lacrimo-nasal duct may be active or passive in the transmission of germs. It may contain septic secretions without a show of pus, and the amount escaping through the puncta into the eye may be so small as to be practically invisible. Even lachrymation may be absent. If the nasal swelling is reduced the turgid condition around the valve of Hasner will be lessened, and the secretions will have a natural downward drainage. Ocular irrigation may aid this somewhat. Pressure on the membranous duct will often empty its contents. The small canula of a lacrimal syringe may be introduced into the puncta and very gentle irrigation attempted. If these measures fail it is evident that a patulous tear duct must be secured either by incision or by rapid dilation. Such surgical intervention naturally demands the services of the ophthalmic surgeon.

As incision often leads to cicatricial contraction I prefer the method of rapid dilation without incision which I have practised for some 14 years past. This is done by first introducing a needle probe into the lacrimal puncta and passing it through the membranous canal to the bone. It is then withdrawn and my conical dilator with a maximum size of a No. 10 probe is passed through the previously stretched membranous canal, and thence, by gentle force, through the bony canal into the nose.

While the general shape of the dilator is conical, it is rounded or bellied just above the point, which allows it to dilate so rapidly that the point does not engage, and the dilator never becomes wedged, as with a simple cone.

The needle-probe has the same quick expansion just back of the point, which is sharper than that of the dilator.

The advantages of this method are the avoidance of cicatricial contraction about the lacrimal puncta, and the preservation of capillarity and syphonic action, thus directing the current of lacrimal drainage toward the

Dr. Ziegler's Lacrimal Dilator and Needle-probe.*

nasal orifice. A repetition of this procedure is seldom required, and the repeated use of probes is thus avoided.

When, however, blenorrhea of the sac, lacrimal abscess, or marked caries is present, incision should be promptly made, rapid dilation performed, and a lead style inserted. This should remain for a week, and be followed by lacrimal irrigation.

In very exceptional cases of corneal infection it may be necessary to prevent the regurgitation of these septic secretions by sealing up the lacrimal puncta with the galvanocautery point, or with a crossed suture.

The Eye.—In simple and phlyctenular ulceration of the cornea the treatment to be employed is somewhat similar. A mild, soothing lotion should be freely applied to the eye, consisting of

Sodium biborate32 gm. (5 gr.)
Boracic acid65 gm. (10 gr.)
Rose water	
Distilled water } of each	30 cc. (1 fl. oz.)

Drop in the eye freely, 4 times a day.

If the iris is at all sluggish atropin should be instilled. If the pupil dilates freely its further use should depend on circumstances. Calomel, or iodoform with compound stearate of zinc, may be insufflated or used in an ointment. Hot stupes for 10 minutes 3 times a day may be beneficial. A pressure bandage is occasionally useful, but should be closely watched, as the added warmth may increase the bacterial growth.

Silver vitellin, known as argyrol, in strengths of from 10% to 20%, will prove beneficial, both by its antiseptic action on the ulcer itself and also by its sedative action on the congested conjunctiva. The staining it causes is only temporary, as it is perfectly soluble in water. It possesses the important advantage of causing neither pain nor irritation.

Sloughing ulcer will require more vigorous treatment. The eye lotion previously mentioned, or mercuric chlorid solution, 1 to 8,000, should be used freely every hour or two. Ice compresses should be applied continuously day and night. Atropin should be instilled 3 times a day. Iodoform may be dusted in, or used as an ointment.

If the ulcer tends to spread, cauterization by the galvanocautery or by carbolic acid may be employed. Corneal electrolysis is equally efficient and less destructive. I prefer, however, a 1% solution of formalin, which is applied daily, under cocain anesthesia. A small bit of cotton is wrapped tightly on the end of a wire applicator. Dip this into the solution, wipe off all excess, and rub lightly but carefully over the ulcerated surface. The healthy tissue should not be touched, as some pain and irritation may result. The formalin method has this double advantage, it does not destroy corneal tissue, and it prevents or clears up a great part of the opacity which is so liable to result. It must, however, be used with great care.

* Made by Ferguson, and by Schneyder & Allen Co., in Philadelphia; by Meyrowitz, in New York, and by Lûer, in Paris.

The System.—The general treatment should be dietetic, hygienic, and tonic.

Errors of diet should be at once corrected. Coffee probably causes the most harm, although sweets are undoubtedly a close second. My invariable formula for children is, "No tea, no coffee, no cakes, and no candy." Salt-water baths with friction, followed by an alcohol sponging, will tone up the relaxed skin. Inunctions of sweet almond oil will stimulate the peripheral circulation, and protect the skin from cold and changeable weather. Proper physical exercise will promote oxidation. The bowels should be carefully regulated. A 1-grain tablet of cascara every night may prove useful. The granular phosphate of soda is a saline aperient, corrective, and cholagog, and especially valuable for children. Calomel is both anti-phlogistic and a stimulant to the dormant lymphatic system. The syrup of the iodid of iron is frequently indicated. When there is debility or prostration, milk punch will revive the vital forces. The following tonic mixture has proved its usefulness:

Mercuric chlorid065 gm. (1 gr.)
Sol. of potassium arsenite	7.5 cc. (2 fl. dr.)
Tr. ferric chlorid	15 cc. (4 fl. dr.)
Diluted phosphoric acid	30 cc. (1 fl. oz.)
Syrup of lemon,	q. s. ad. 120 cc. (4 fl. oz.)

Take a quarter to one teaspoonful in water after each meal. (Dose according to age.)

To epitomize the treatment briefly:

1. The nose should have antiseptic irrigation and local treatment applied.
2. The lacrimonasal duct should be disinfected or dilated.
3. The eye should have a soothing lotion, a mydriatic instilled, and a cauterant applied to the ulcer, if necessary.
4. The diet should be regulated, tonic and anti-phlogistic treatment given, and the hygiene generally improved.

Free Pasteur Institute at New Orleans.—The Charity Hospital in New Orleans, an institution founded in 1727, has lately added to its equipment what is the only Pasteur Institute in America offering free treatment of hydrophobia. The hospital, which is one of considerable repute, has a capacity of 900 beds, and handles something over 7,000 cases each year. Its fine system of free clinics, the perfectly equipped amphitheater, and the efficient ambulance service make it one of the most complete institutions of its kind in the world. But its most distinctive and praiseworthy feature will be the new Pasteur cure. It is to be absolutely free to the people of Louisiana and the neighboring States of Alabama and Mississippi. These 3 States furnish a very large percentage of hydrophobia victims. During the past year Louisiana alone sent 36 cases to Baltimore for treatment at the Pasteur Institute, 34 to Atlanta, and 23 to Chicago, a total of 93. New Orleans has more stray curs on its streets than any other city in the world, and judging from the hydrophobia records, they all seem to get in pretty effective work.—[*Boston Transcript.*]

Report of Factory Inspectors.—The annual report of the State Department of Factory Inspectors, for the fiscal year ending October 31, 1903, shows that during the year a total of 367 fatal and 2,406 nonfatal accidents occurred in the establishments over which the Department has control. Of the fatal accidents 207 were either the result of unavoidable causes or accidents, and 1,550 of the nonfatal accidents were of like character. The estimate of the Department, based upon returns from every county in the State, shows that not more than 36,000 boys and girls between the ages of 13 and 16 years are employed in the several industries over which the Department has jurisdiction, and that 6.5% of this number were illegally employed at some time during the year covered by the report. The report also states that an analysis of the inspection of "sweatshops" does not indicate that these shops are a menace to health and safety of those employed therein or to the public, and that the sanitary requirements of the law have as a result been observed by the proprietors of bakeshops. The report indorses the act enacted by the last Legislature for the inspection of vessels engaged in carrying passengers upon inland lakes.

1.—Ethyl Chlorid in Gynecology.—E. E. Montgomery and P. B. Bland recommend ethyl chlorid to allay pain and relieve muscular contraction in abdominal pelvic examinations on account of the short time required for anesthesia, the quickness of recovery, and the little tendency to nausea and vomiting, thus permitting its use in office practice. It is indicated also in minor operations such as vaginal incision for pelvic drainage. Its most effective employment is as a preliminary to ether or chloroform, distress and sensation of asphyxia being thus avoided. They believe it decidedly safer than chloroform or ethyl bromid, and possibly safer than ether. The disadvantages are the expertness required to avoid profound anesthesia and at the same time emergence from its effects at an important stage of the operation. The expense prevents its use in a general clinic. [H.M.]

2.—Etiology of Tabes Dorsalis.—A. C. Brush believes the disease can be as clearly attributed to other causes as to syphilis. In his own cases he assigns to syphilis 59.9%; alcoholism 5.7%; secondary to multiple neuritis 4.3%; spinal injuries 4.3%; injuries to the lower limbs 2.9%; blows on the back 4.3%; rheumatism 1.4%; sexual excess 1.4%; diphtheria 4.3%; unknown 11.5%. The method by which syphilis acts has not been explained. Possibly it is through its effect on the scanty vascular supply of the posterior columns. He explains the causal relation of trauma as follows: Disease of the peripheral portion of the spinal neurons may ascend to the columns and gray matter of the cord; and thus disease of the sensory fibers which ascends to the posterior ganglia may, by causing disease in them, cause similar conditions of their central branch and thus ascend to the posterior columns. Concussion, confusion or hemorrhage into the cord may be caused by the injury, and a subsequent thickening of the meninges may compress the cord and peripheral nerves, with secondary degenerative changes. Alcohol acts through its toxic effects on the nervous system and its power to produce vascular disease. The other causes may be classified as toxins due to contagious disease, toxins from perverted metabolism, and those factors which lower general vitality. [H.M.]

3.—See American Medicine, Vol. V, No. 23, p. 598.

4.—Gonococcus Metastasis.—J. McColgan and J. M. Cooper review the already recorded cases of suppurative lesions other than those in the urethra in which attempts have been made to demonstrate the gonococcus, and report one of their own in which an abscess occurred in the hand. The fact that such metastatic abscesses occur in the absence of urethral symptoms establishes the importance of routine examination of pus from such lesions. The liability of such a patient to contract ophthalmia or infect others is much greater than when the disease is localized in the urethra. It is probable gonococci will be found in greater number in the urethra whether there is a urethritis or not, and proper treatment directed to this condition should be instituted to prevent other metastases. [H.M.]

5.—Typhoid Perforations.—L. Frank states that perforations are to be expected in about 2.5% of all cases of typhoid. Prompt surgical intervention is the only treatment. Early diagnosis will greatly reduce the mortality as 55% to 60% would recover. This requires careful watching and proper interpretation of symptoms. The sphygmomanometer should come into general use. More patients die from delay than errors in

surgical technic, therefore in doubtful cases operate. No patient, unless dying, is beyond hope of saving. Be sure to drain. [H.M.]

6.—Localizing Foreign Bodies in the Orbit.—V. H. Hulen disapproves of the Haab magnet as a means of diagnosis and of attempting to remove a piece of steel before its location is known. He describes a "localizer" which can be made by any carpenter, illustrating the same by cuts. A piece of lead is fastened by adhesive plaster to the lower lid directly under the center of the pupil. The distance of this from the center of the cornea and its distance posteriorly or anteriorly from the apex of the cornea is measured. After making a photograph with the Crookes tube the latter is raised a definite distance and another photograph is taken. With these two plates and the accurate measurements one can quickly determine the exact position of the foreign body. The method by which he accomplishes this he describes in detail. [H.M.]

7.—Strictures of the Female Urethra.—H. L. E. Johnson finds that a large number of standard authors fail to mention this disease. Diagnosis is by olive pointed sounds, bougies, or metal catheters. The condition of the urine, even in advanced cases, is often misleading. No physical examination in "disease of women" should be considered complete until the catheter has been passed into the bladder. Prognosis is favorable in acquired cases, except when advanced bladder or kidney disease exists from infection or distention. Treatment consists in gradual or rapid dilation, and in some cases incision. [H.M.]

9.—Dental Disease in Ocular Disturbances.—W. O. Nance notes the close anatomic relations between the alveoli and orbit. Often the roots of the teeth extend into the antrum and disease reaches the orbit through the thin partition of bone. The ocular disorders ascribed to dental disease are orbital cellulitis and abscess, conjunctivitis, keratitis, corneal ulcer, iritis, scleritis, papillitis, mydriasis, lacrimation, amaurosis, amblyopia, strabismus, ptosis, interference with accommodation, and paresis or spasm of the several muscles of the eye and lids. The number of cases which a review of literature and the writer's own observation demonstrates suggests the necessity of a thorough examination by a competent dentist in those instances presenting uncertain causative phenomena. [H.M.]

Boston Medical and Surgical Journal.

1. Forceful Correction in Lateral Curvature of the Spine. Fourth paper. ROBERT W. LOVETT.
2. Hydrotherapeutic Prescriptions. JOSEPH H. PRATT.
3. An Account of the Work, Including Obstetric Technic, at the Lying-in Hospital of the City of New York. CHARLES H. BRADLEY.

1.—Forceful Correction in Lateral Curvature of the Spine.—Robert W. Lovett holds that the best chances of improvement in severe cases of scoliosis are given by, (1) the use of a severe force to secure an improved and if possible and over-corrected position temporarily, and (2) to retain as much as possible of the position thus secured during part of the growing period. He recommends, with some modification, the method of Wullstein, whose plan is to forcibly extend the head while the patient's pelvis is strapped to a seat which can be tilted to make the pelvis oblique, and which also can be rotated to change the relation of the pelvis to the spine. Lateral pressure is made by pads running in horizontally from the sides of an apparatus which is described. By combined motion of the seat and adjustable pads, any degree of twist in the spine upon the pelvis may be produced. Wullstein uses at times a force of 250 pounds in the pull, and applies a plaster jacket while the patient is thus stretched and pushed into a corrected position. The jacket embraces the chest, shoulders, and head. Lovett does not believe that Wullstein's attempt to correct rotation by torsion of the whole spine is based on correct principles, nor that torsion can be so corrected, but with this unimportant exception he believes the method is progressive, rational, and effective. Lovett's paper is interesting and exhaustive. He explains his belief in this form of correcting scoliosis by various illustrations. [A.B.C.]

2.—Hydrotherapeutic Prescriptions.—J. H. Pratt quotes Cohen as suggesting that there should be in every city an insti-

tution to which any physician might refer his patients with a definite hydratic prescription, just as he can now send them to the apothecary. Precision of method is essential to success. In view of the institution already established in Boston he outlines the proper treatment in chlorosis and other forms of anemia, chronic muscular rheumatism, chronic arthritis, neuralgia, disease of the spinal cord, exophthalmic goiter, chronic pleurisy, cardiac insufficiency, gastric and intestinal disease, hypertrophy of the prostate, neurasthenia, hysteria, chorea, chronic nephritis, obesity, and diabetes, annexing 35 definite prescriptions applicable to one or more of the conditions described. [H.M.]

Medical Record.

10. A Radiographic Surprise. W. I. LEFEVRE.

1.—Hip and Thigh Amputations for Sarcoma of the Femur.—George F. Shradly reports that in 1882 he did a thigh amputation for sarcoma of the internal condyle of the femur, and the patient is well today. He deemed it wiser, at the time, to do a disarticulation at the hip-joint, but this the patient refused. The author reports the case because of its rarity, and enters into a discussion as to the relative merits of amputation in the thigh or disarticulation at the hip-joint. From the literature he is unable to find that disarticulation at the hip-joint gives better results than amputation through the thigh. He believes there is a certain susceptibility to neoplasms in some individuals which helps to account for malignant growths. He quotes Henry T. Butlin, who collected 68 cases of hip amputation for sarcoma of the femur and but one patient remained well sufficiently long to be considered cured. Other authors are quoted, particularly W. B. Coley, Frederick S. Dennis, John A. Wyeth, etc., and of the whole number of cases reported there were barely 11 that outlived the three-year period. [A.B.C.]

2.—Thoracic Aneurysm.—C. E. Nammack believes this is not so rare as has been stated. The diagnosis is determined by the recognition of the causative conditions, the symptoms, and physical examination. Any tumor lying across an artery will have pulsation communicated to it, but the pulsation will not be expansile as in aneurysm. Aspiration is a final test. The value of the röntgen ray is considerable. The danger of Porter's method of diagnosis with an esophageal tube distended with water outweighs its advantages. The writer has verified the accuracy of Eccles' sign in a number of cases, a sensation of dread, faintness, or giddiness, when the head is thrown back as in shaving. [H.M.]

3.—Dacryocystitis.—A. Wiener in partial stenosis syringes the sac, using massage, together with proper treatment of the nose. If there is organic stricture and the contents of the sac are not purulent he removes the anterior portion of the inferior turbinate, its lacrimal process, and the inferior turbinated crest on the superior maxillary bone. He then slits open the nasal duct to the neck of the sac. The indications for extirpation are fistula (acute cases excepted), chronic blenorrrhea, chronic catarrh with organic stricture, chronic blenorrrhea with caries, and fresh blenorrrhea in ulcer serpens or when operation for cataract or glaucoma is contemplated, in fresh injuries of the cornea, or in tuberculosis of the sac. He describes the technic of the operation. Epiphora does not follow, except on exposure to sudden changes of temperature. Should it be annoying, the gland may be removed. The conjunctiva contains enough mucous glands to keep the eye moist. [H.M.]

4.—Thymic Tracheostenosis.—W. W. Carter reports a case suggesting the following: In laryngeal stridor it should always be determined whether or not the thymus is enlarged. As surgical shock is badly borne by infants, especially those in

this condition, if the symptoms are not urgent, postural treatment should be tried, and if in any position of head and neck, relief is afforded, that position should be maintained by apparatus until nature has effected a cure by enlargement of the thorax, strengthening of the tracheal rings and diminution in the size of the gland. Intubation, tracheotomy, and artificial respiration do no good. Opening the mediastinum, bringing forward the gland, and stitching it to the tissue over the sternum should be done immediately if there is danger from asphyxia. [H.M.]

5.—The Kollmann Five-glass Test.—G. T. Mundorff states that, while the urethroscope is specially valuable in making a diagnosis of intraurethral morbid conditions, there remain some cases in which, for various reasons, the use of the urethroscope is not practical. In these, and as a confirmatory test in others, he recommends the five-glass test of Kollmann. The plan of procedure is as follows: After cleaning the meatus, the physician introduces a catheter up to the external sphincter, care being taken not to force it beyond this point. Steadying the catheter in this position by grasping the penis with the left hand and holding the catheter by the forefinger and thumb of the same hand, the physician attaches a syringe filled with a mild boric acid solution, and gently forces the fluid into the urethra. The returning fluid is allowed to fall into a urine glass held by the patient. The physician examines this and notes the presence of shreds and mucus. The irrigation is continued until no more shreds are found in the irrigating fluid. Ten to 15 irrigations may be necessary before this result is reached. The physician allows the fluid returning from the last injection to remain in the glass held by the patient, and designates this as No. 2, or the "control glass." The catheter is then withdrawn and the patient is permitted to urinate into the remaining 3 glasses, numbered respectively, 3, 4 and 5. Glass No. 3 should always be regarded as doubtful, since it is possible that some shreds in the anterior urethra did escape the irrigation. Shreds in glasses Nos. 4 or 5 signify pathologic changes in the posterior urethra, bladder, and possibly kidneys. [A.B.C.]

6.—Antistreptococcic Serum in Smallpox.—A. C. Smith reports a series of cases treated with the serum with a shortening of duration, absence of secondary fever, prevention of pus formation, and thus of absorption of septic matter. No pitting, no marked debility, less suffering, and much less danger of lung and kidney involvement with a much more rapid convalescence. The serum should be used early and in sufficient quantities to completely neutralize the toxins of the disease. The writer has given two doses of 20 cc. each. [H.M.]

7.—Early Treatment in Arterial Degeneration.—L. F. Bishop notes that the degeneration of function is more striking during life than degeneration of tissue and we must be guided by the former. The earliest sign is an irregularity of tension going on to pretty high arterial tension. The defect is concealed by compensatory hypertrophy. The expectation of life is in inverse proportion to the postponement of treatment. [H.M.]

10. The Influence of Typhoid Fever on the Nervous System. C. C. HERSMAN.

1.—Repair of Laceration of Cervix.—R. L. Dickinson says the best time to repair a laceration of the cervix is when swelling has subsided and the parts are fairly normal in contour and proportion if not in size; when ether can be given;

when bleeding will be slight; when the surfaces are yet raw and ready to unite; when no contractions or inflammatory processes have altered the structures; and when patient and doctor are ready for unhurried work. Such favoring conditions are to be found from the third or fourth to the fourteenth day, more or less after delivery. His practice is (1) to suture cervical injuries at the close of labor when they seem to be the cause of postpartum hemorrhage; (2) to sew up all cervical tears in the first week in conjunction with the perineal operation when the pelvic floor injury is of such character that a few days' delay is desirable; and (3) to restore severe injuries to the cervix from the third to the tenth day after delivery. [C.A.O.]

2.—Cerebral Diplegia.—The case reported by P. W. Nathan is of special interest, not alone on account of the hypertrophy of the calves, but also because of the difference between the circumferences of the two sides of the body, which apparently were similarly affected by the palsy. The illness of the patient, a boy aged 10, dates back to six weeks after birth, when he had convulsions. These recurred at the age of one and a half years, and from that time until the seventh year he was subject to attacks of a peculiar and constant character. From the seventh year to the present time he has been free from attacks, and during that time has been much improved in health. He began to walk at the age of three, but at present is unable to walk at all. He stands with feet in the equinovarus position, and is very unsteady. When standing there is a decided lordosis of the spine. The calf muscles stand out prominently, and are evidently hypertrophied, which, together with the lordosis, gives him very much the appearance of a patient with pseudohypertrophic paralysis. Nathan says so far as he can determine, this is the only case on record in which the pseudohypertrophy occurred in a case of so-called spastic spinal paralysis; all the previously reported cases were hemiplegias. [C.A.O.]

4.—Primary Trachelorrhaphy.—G. H. Donahue says the best time to repair the cervix is from 24 to 36 hours after confinement. The torn surface will then still be fresh enough to obtain perfect union. Right after delivery the cervix is so soft and swollen and edematous, as to be distinguishable from the vaginal wall only with difficulty. Twenty-four to 36 hours later it will have regained its individuality, and the os and the canal will be easily recognized. With proper precaution, antiseptic and otherwise, the operation at this time is well borne; it is safe, it is easy to perform, and it is likely to be successful. If successful, it assures normal involution with all its health-promoting consequences, as against possible subinvolution with its interminable and baneful sequels. [C.A.O.]

5.—Laparotomy for Gunshot Wounds.—R. W. Johnson reports five successful cases. The first is that of a girl of 18, whose abdomen had been penetrated near the median line by a 32-caliber ball. The wound in the stomach was about 5 cm. (2 in.) in length and the liver which was perforated about 2.5 cm. (1 in.) from the lower edge of the right lobe was bleeding profusely. The wound in the stomach was closed by interrupted Lambert suture, the liver sewed up with catgut, and the abdomen closed without drainage. The second case is that of gunshot wound of the liver in a man of 22; 27 hours after the injury the abdomen was opened and the liver found perforated. The third case is also one of gunshot wound of the liver, occurring in a boy of 12. The liver had been furrowed by a bullet of 38 caliber, which was found in the upper surface of the liver under the diaphragm. The fourth case is one of gunshot wound of intestine. The ball had ploughed across the gut without entering its lumen. The edges of the furrow were brought together with Lambert sutures. The fifth case is that of a negro of 17 who was shot in the left side just above Poupart's ligament. A median incision was made below the umbilicus and the belly found to be full of blood; 17 perforations of the small intestine and 11 of the mesentery were successively closed by silk Lambert sutures. He was discharged cured three weeks later. [C.A.O.]

6.—Sodium Cinnamate in Tabes.—Paul Bartholow has used subcutaneous injections of sodium cinnamate in several cases of locomotor ataxia with gratifying results. The site of operation was the interscapular space. The formula used follows: Sodium cinnamate, 10 parts; sterilized water, 100 parts. —M. The solution should be kept in dark-colored bottles, or

be freshly prepared for each injection. As a rule three injections a week were deemed sufficient; sometimes, though rarely, one was given daily until some evidence of excess appeared, as indicated by a temporary irritability of the stomach. Beginning with 20 m. the amount was slowly raised to 60 m. In conclusion he says that sodium cinnamate benefits the organism in two ways chiefly: 1. By promoting appetite and digestion and, consequently, nutrition. 2. By setting up chemic changes in the outlying regions of degeneration, in the cells and connective tissue of the nerve substance. [C.A.O.]

9.—Diseases of Gallbladder.—C. A. Elsberg discusses some clinical features of diseases of the gallbladder and bile ducts due to gallstones, and states some of the indications for their surgical treatment. He says that no operation should be performed in (1) cases with mild symptoms, especially if the diagnosis is in doubt; (2) cases with recurrent mild attacks with long intervals of health; (3) acute obstruction of the common bile duct; (4) and in any disease which would contraindicate a surgical operation of any kind, unless under vital indications. Operative interference is indicated in (1) acute inflammatory diseases of the gallbladder with signs of severe infection or peritoneal invasion; (2) cases with very frequent mild attacks, which incapacitate the patient for work, which are accompanied by much loss of flesh and strength, or in which the patient is in danger of acquiring the morphin habit; (3) persistent biliary fistula; (4) rare cases in which the symptoms are due to adhesions of the normal gallbladder to neighboring organs; and (5) chronic obstruction of the common bile duct. [C.A.O.]

1.—Specific Therapy of Tuberculosis and Vaccination against the Disease.—E. Maragliano, as a result of 15 years' research, states that it is possible to produce a specific therapy and to immunize against tuberculosis, and that there is good reason to hope for an antituberculous vaccination for man. He has produced serums with an agglutinating power of 1 to 2,000 and 1,000 antitoxic units to 1 cc. By exact measurement, he has found that the serum increases the defensive substances of the blood in more than geometric proportion, showing that the organism plays an active part in this increase. There follows disappearance of fever, sweats, cough, and bacilli, and foci of bronchopneumonia, the production of connective-tissue foci, and improvement in general nutrition. He gives the statistics of cures. In animals immunization has been demonstrated by means of intravenous injections of virulent cultures. He describes immunizations by attenuated cultures and by dead bodies of bacilli by the expressed and filtered juice of bacilli. These materials may be given subcutaneously, intravenously, or by mouth. The leukocytes are much richer than the plasma in antitoxins and antibodies. The latter are found in the milk of immunized animals. This milk and the flesh also of immunized animals used as food will produce corresponding immunity. By creating a focus of tuberculous inflammation without living bacilli the active production of defensive materials is brought about. In this way a true vaccination may be practised. Slight feverishness is the only disturbance. The abscess lasts three or four months. Analogous results are seen in cured cases of surgical or cutaneous tuberculosis, in which foci do not develop elsewhere. [H.M.]

2.—Treatment of Neurasthenia.—H. T. Pershing classifies remedies into whatever tends to check the loss of nervous energy or to increase its income, providing it is not incidentally harmful. Rest is of no avail if worry goes on. Treatment must largely be determined by the characteristics of the physician. If he is buoyant he will depend largely on mental influence, if scientific on physical treatment. Loss of nervous energy is checked by prevention of emotional disturbances,

reassurance and favorable suggestion, by forming habits of muscular relaxation and repose, limitation of work, prevention of toxic conditions, removal of peripheral irritations, reduction of cortical irritability by medicines and by sleep. Remedies which increase nervous energy are food and medicines. Remedies used empirically whose action is complex or obscure, are electricity, massage, hydrotherapy, exercise, change of climate, and these are the least important. A valuable resource in controlling a depressing emotion consists in the voluntary suppression of its motor reaction and the imitation of the attitudes and actions which express the opposite emotion as in cultivating the bearing of courage and repose. The writer believes long continued doses of bromids aggravate the disease, and prefers codein or opium. He prescribes the latter with strychnin and laxatives so the patient has no discretion as to dosage. [H.M.]

3.—Abdominal Ascites with 150 Tappings.—In the case reported by E. K. Browd, the tappings have extended over 10 years, the patient refusing radical operation. She is now 69 years old, is in fairly good condition, and is not bedridden except for a day or so after each tapping, which is done biweekly. She has lost altogether 1,441½ quarts, or 360½ gallons, of fluid. [H.M.]

4.—Gastroenterostomy Without a "Loop."—John Rogers recommends the method prescribed by Petersen and used in Czerny's clinic. The latter surgeon reports 215 cases without an instance of serious vomiting. It is based on the fact that the first few inches of the jejunum descend vertically behind the stomach, and in this part lie directly in contact with the posterior surface of the stomach, separated from it only by the nonvascular portion of the mesocolon. The ordinary retrocolic posterior operation is performed by drawing the omentum and transverse colon out of the median epigastric wound, and stitching the margins of the exposed posterior surface of the stomach near the greater curvature, to the edges of a rent made in the mesocolon. The jejunum near its origin is held perpendicularly to the spine, and attached some 2 in. to 4 in. below its origin at the plica duodenojejunalis, to the exposed posterior surface of the stomach by a row of Lembert sutures placed transversely to the long axis of the gut, and in its free border. In front of this the stomach and intestine are opened with due precautions, and the fistula completed with stitches or the Murphy button and surrounded externally by a continuation of the Lembert stitches. The jejunum is thus anastomosed to the posterior surface of the stomach in its normal descending position and without any twists. There is no loop to become occluded, and no chance for volvulus or hernia above it. Rogers reports in detail five cases successfully operated upon by this method. [A.B.C.]

5.—Home Treatment of the Tuberculous.—H. Levien emphasizes the need of educating the public as to the importance of fresh air and nourishing food and rigid supervision by physicians and nurses. This can be best attained by sanatoriums in sufficient numbers to supply the demand. "Home treatment" is meaningless and may prove a menace and mislead the public and the term should not appear in the medical press. [H.M.]

6.—Dropsy.—A. C. Morgan defines this and synonymous terms. When unilateral the cause is to be found in immediate proximity as an obstruction to the return circulation. In bilateral edema the cause is generally central. Local edema may be acute, caused by abscess, subacute as from a rapidly growing tumor, chronic as from lymphangitis, operation scars, etc. Section of a nerve causes local edema through dilation of the arteries. Edema of the ankles is often caused by anemia which in turn may be due to any cachexia. In a transudate the skin is cold, symmetrically swollen, pale, shiny, and slowly resumes its former shape on removal of pressure. With an exudate it is hot, nonsymmetric, red, pitting quickly disappears. Edema of the arm or neck including the upper thorax may be due to aneurysm or mediastinal growths or an enlarged auricle pressing on the vena cava. The initial dropsy of Bright's appears in the lower eyelids, of valvular heart disease in the ankles, of failure of compensation in the portal circulation in the abdomen. General dropsy may be recovered from if the patient is in the prime of life with good muscles, and the

poison or factor causing the condition can be removed. When it occurs in cachectic conditions it can be inferred the last stages are near. [H.M.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

Lymphatic Varices.—It is evident, and microscopic researches have demonstrated, that in the vast majority of cases, if not to say all, lymphatic varices simply represent a manifestation of filariasis. Infrequent are the instances where one has not been able to discover the embryos in the fluid coming from the varix or in the patient's blood, and even admitting that the examination has remained negative, one must not conclude that the subject does not possess the parasite. To find the filaria it must be searched for at the proper time, when the patient is quiet, preferably in deep sleep. Several careful examinations may be required and it must also be remembered the difference in number of embryos will vary greatly in the same individual in the interval of several days. It is true that the adversaries of the origin of lymphatic varices from the filaria point out, that these lesions only occur in subjects born in hot countries or at least having resided in them for several years, but we must admit the climacteric influence necessary for the lesions of filariasis to become manifest. Although obstruction arising in the thoracic duct is not the cause of lymphatic varices, a more or less complete obliteration of the lymphatics is a necessity, if not in itself sufficient, for the production of this lesion. Adult filaria coiled up so as to completely obstruct the lymph current have been found in the lymphatics, and although the size of the parasite will not permit it to pass through the lymph-nodes, a case is recorded by Schwartz of a patient afflicted with lymphatic varices and in one of the extirpated lymph-nodes was found an adult filaria in the center of a nodule composed of giant cells, the so-called pseudotubercle of filariasis of Marie. This must however be exceptional and usually thromboses caused by enormous agglomerations of embryos produce an obstruction to the lymph current. When examined, the lymph will be found literally teeming with embryos. The most frequent site for the lesion is in Scarpa's triangle, the lymphatics of the spermatic cord or those of the groin being involved, either separately or both at the same time. The dilation continues beyond the lymph-nodes in the abdominal lymphatics and even extends to the thoracic duct. The pathology of this lesion varies and presents various degrees. In some the varices will collapse when punctured and this would lead to the conclusion that the lymphatics were merely distended, but in other instances the lymphatics appear as dry, knotty cords. The histology of this pathologic process is similar to that of varicose veins. One finds an irregular hypertrophy of the walls of the lymphatics, hyperemia of the adventitia, inflammatory foci especially numerous around the capillaries, and lastly a proliferation of the elastic tissue. The lymph-nodes receiving the diseased lymphatics take part in the processes; the node takes on a cavernous aspect the result of chronic sclerotic inflammation accompanied by an hypertrophy of all the connective-tissue structures. The follicles are increased in size but apparently are not histologically changed. The clinical signs naturally vary with the seat of the lesions, but the varices are more frequently found in Scarpa's triangle, commencing in the lymphatics of the spermatic cord. In the early stage, examination would lead one to conclude that the case was one of varicocele, but later, when the dilation becomes more marked, when the testicle becomes involved in the process, the condition may be easily mistaken for tuberculosis, for hydrocele or what is more likely, a hernia. A careful examination with a detailed

history of the case, should however prevent such diagnostic errors from occurring.

REVIEW OF LITERATURE

Chlorid Metabolism in Chronic Nephritis.—E. v. Kozičkowski¹ says that sodium chlorid holds a special position, and cannot be used as an indicator of the behavior of other salts, especially in nephritis. In health the excretion of chlorids varies with the ingestion of salt, of water, and with other conditions. In nephritis without edema there is a remarkable regularity in their excretion. The amount of sodium chlorid in the urine varies inversely with the extent of edema present, and is independent of the amount of water excreted by the kidneys. The retained chlorid is not contained altogether in the edematous fluids, but also is found in the tissues themselves. The retention of salt is probably due to disturbances in the circulation. The excretion of phosphates and sulfates does not undergo the variation seen in the case of the chlorids, but increases and decreases with the amounts ingested, whether the kidneys be healthy or diseased. The chlorid excretion may be taken as an index of the prognosis in renal disease. Increased excretion following retention is a favorable sign. Considerable diminution in the chlorids is a bad prognostic sign. The author believes the retained salt to be an important factor in the development of edema. Hence, the mean employed to combat edema should have for their object the removal of sodium chlorid from the body. The ingestion of salt should also be restricted. [B.K.]

Bronchial Asthma the Type of Nervous Catarrh.—Schmidt² finds, from a scrutiny of literature and personal work, that the Bienger-Curschmann asthma theory, which considers spasm of the bronchial muscle fibers the deciding factor in producing asthmatic attacks, possesses numerous weak points. They are: No one has ever been successful in producing an asthmatic attack experimentally, although the pneumogastric nerve, the motor nerve of the bronchial muscle, has often been irritated. During such an experiment the bronchial lumen contracts, showing that the bronchial muscle is irritable, but this has always lasted but a short time and has affected the lungs but slightly. The respiratory mucous membrane participates in every asthma attack. Postmortem findings have shown that asthmatic attacks occur in cases in which the bronchi have been dilated, and under conditions making spasmodic cramps of the bronchial muscle improbable; such attacks have occurred in cases in which a large number of the smallest bronchi are occluded by a stringy secretion. In fact, the mechanical occlusion of the bronchioles or the inflammation of the mucous membrane is sufficient to produce and explain such attacks and the presence of such a focus within the respiratory mucous membrane must therefore be considered as the principle cause of the asthmatic attack. For the origin of a number of peculiarities, which the attack offers, the causal agency must be found in the nervous system. The nervous components are the sudden exacerbation of the catarrh, the hypersecretion, and the concomitant bronchial cramp. [E.L.]

Yellow Fever.—C. J. Finlay³ says all transmission is caused by the mosquito, and when this disease is so carried the mosquito must have punctured the original patient during the first three days of illness, to obtain virus in an effective state. How long the mosquito retains this, effectually, is not established. The only variety of mosquito known to carry the virus of yellow fever is *Stegomyia fasciata*. The period of initial incubation is from 40 hours to 13 days. The injection of sanguineous serum obtained from convalescents will act as an effective measure of prophylaxis. While the virus of yellow fever will continue active after five days if blood-serum containing it, be guarded from the air, with free access to air the virulence disappears in about 48 hours. Blood-serum from a person suffering from yellow fever, if injected into the subcutaneous tissue of a well person, reproduces the disease. The writer so long ago as 1898 has written concerning a "method of vaccination against yellow fever." [T.H.E.]

Excretion of Nitrogenous Substances in the Urine in Acute Infections.—F. Erben¹ examined the urine in measles, scarlatina, varicella, typhoid fever, and a streptococcus angina. In all cases during the period of elevated temperature, an increase was found in the nitrogenous excretion, depending chiefly on an increase in the urea. The increase was in proportion to the height of the temperature, and was more marked in the diseases of short duration than in the longer ones. A distinction is made between the nitrogen precipitated by tungstophosphoric acid and that not precipitated. During the fever and the first few nonfebrile days, there was a much greater increase in the precipitated nitrogen than in the nonprecipitated. The ammonia was found to run a course parallel to the nitrogen. The intermediate products of proteid decomposition, namely, uric acid, xanthin bases and amids, were regularly increased during the fever. This seems to depend upon the increased proteid decomposition within the organism. In scarlet fever, and to a lesser degree in typhoid fever, there was a preponderating increase in the nonprecipitated residual nitrogen (amids); this is traced to the resorption of lymphatic tissue during recovery from these diseases. [B.K.]

Antityphoid Inoculation.—A. E. Wright² concludes his article on antityphoid inoculation, which has parts in 3 numbers of the journal. Part I explained the general principles of the physiology of immunization; Part II, the application of these principles to immunization against typhoid fever; Part III deals with the technic of antityphoid inoculation, the clinical symptoms following inoculation, and statistics showing the results. The latter include many thousands of cases, mainly of soldiers in the British army, contrasted with cases under the same circumstances that were not inoculated. The results of the antityphoid inoculation are given under the following heads: (1) The effect on the incidence of the disease. The incidence of typhoid fever was diminished by at least half in the inoculated; (2) the effect on the case mortality. This has been rather less than half that among the uninoculated; (3) effect on the deathrate from the disease. This has often exceeded, and seldom fallen below, a four-fold reduction; (4) duration of the protection conferred by inoculation. This persists during the second and probably during the third year. It is not infrequent to find an agglutinative power in the blood of inoculated persons as long as 2 years after inoculation. [A.G.E.]

Tachycardia.—Fernet³ advises the application of cold compresses to the precordium; there is a reaction of the muscles which seems to include those of the heart, and the patient is relieved. Formic acid is to be given cautiously. It is known to remove that sense of fatigue with which some people suffer. The acid, regularly taken, markedly increases the power of muscular activity. But it may be necessary to reduce the dose, or to withdraw the acid for a time, on account of its vasodilator properties. [T.H.E.]

Physiology of the Esophagus and Cardia.—From experiments in man and animals, J. von Mikulicz⁴ finds that the esophagus in the adult is closed only in the cervical part. The thoracic part is an open tube, containing air. In a state of rest the pressure is a little less than that of the atmosphere; it is diminished during inspiration, and increased during expiration. In swallowing, the pressure rises a little higher than in forced expiration; a part of the contained air is always retained, all of it being expressed only during violent coughing. During rest the cardia is completely closed by means of the tone of the circular muscles, and also by a valve-like arrangement. It is readily opened for fluids and gases passing from the esophagus into the stomach, but is opened with difficulty by currents passing in the opposite direction. The cardia is automatically opened from the esophageal side by a pressure less than that of a column of fluid filling the thoracic part of the esophagus. [B.K.]

Open-air Treatment of Bronchopneumonia Complicating Whoopingcough.—C. B. Ker⁵ has succeeded by this treatment in considerably reducing the deathrate in the Edin-

burgh City Hospital. Those who see whoopingcough only in good class practice do not realize how serious it is liable to be in the children of the poor. In Edinburgh nearly one-third the zymotic deathrate is caused by this disease, bronchopneumonia undoubtedly being responsible. In this complication, rest, which is so important, is impossible on account of the cough, and patients are hard to feed and lose what they take by vomiting. The lung often becomes tuberculous. Tuberculosis and the fact that some children contracted the bronchopneumonia in the wards suggested the open-air treatment. The experiment was begun with four children who were left out six hours daily in clear weather. These were the worst in the wards and regarded as hopeless. There was marked improvement in some of them, though the recovery rate was not the same as with those treated later from the start. The main contraindication is laryngitis. The children were warmly covered and the chests protected with cotton wool. Screens were placed to the windward side of the cots. The whoops were unaffected in number or severity. The patients took food ravenously and strength increased. They slept better. Convulsions did not markedly decrease, but the whole nervous tone seemed better. The temperature was not affected so rapidly as expected, but there was usually steady improvement of all symptoms. Owing to the better ventilation of the ward, bronchopneumonia of hospital origin became extinct. Under the old regime two out of three children with bronchopneumonia died; under the new, two out of three recovered. [H.M.]

Cases of Incipient Tuberculosis Suitable for Sanatoriums.—C. H. Cattle,¹ after considering the diagnosis of incipient tuberculosis, makes the following suggestions regarding the selection of cases for sanatorium treatment: 1. Cases in which the disease is limited to one lobe of one lung without clinical signs of cavity, and where the temperature does not range much above the normal after the patient has been put at rest for one or two weeks. 2. A great many cases of pleurisy, after the active symptoms have subsided, would be better for a three months' course at a sanatorium, because a considerable number of pleurisies are tuberculous. 3. Acute cases which show an early tendency to cavity formation should be ineligible for sanatoriums that aim at cure within a limited period. 4. The possibility of relapse ought to enter into our calculations before sending poor patients to sanatoriums. This raises the question whether the provision of sanatorium treatment is in all cases the best method of applying charitable assistance for the comparatively poor. Many of them can take the few dollars saved or obtained from friends and sustain themselves in the country for several times as long as the fund would last at a sanatorium. The former plan is undoubtedly better for those patients in whom there is strong probability of a relapse after the brief sojourn possible at a sanatorium. [A.G.E.]

Influence of Fever and Other Factors on Sweat Secretion.—The experiments of G. Lang² show that about 13 gm. (3.5 dr.) of water are given off per hour, per square meter, by the skin, both at normal temperature and in fever, provided the stomach be empty. After taking food, the output of water increases about 50%, both in fever and in health. Antipyrin was administered to persons with normal temperature, and it was found that 20% less water was secreted in these persons than in the control experiments. In fever, antipyrin increases the amount of perspiration, and thus increases the heat dissipation. During sleep the evaporation of water from the skin is lessened. [B.K.]

Anal Dilation for Mucomembranous Colitis.—Roussel³ has cured five successive patients by treatment in the form of forced dilation of the anal sphincter. The revulsive effect seems to bring about the favorable result. [T.H.E.]

Idiopathic Dilation of the Esophagus.—Lossen⁴ reports five cases. The etiology is not clear, but he is inclined to the view of Kraus, that there is spasm of the cardia, and at the same time a defect occurs in the muscle about the cardiac opening. He further says that several combined factors may be concerned in the production of the condition, such as

primary atony of the esophagus musculature, congenital defects, or primary esophagitis. Some of the patients complained of pain, some had a feeling that the food would lodge before reaching the stomach. Some patients succeed best in getting liquids, others solids into the stomach. Lossen says the patients utilize various methods in order to force the food into the stomach—some swallowed air, others threw back their heads, putting the esophagus upon a stretch, and in that way forced the food onward. The diagnosis in his cases was easy because he was able to pass the bougie into the stomach without changing its course, thus ruling out a diverticulum. The fluid obtained was free from hydrochloric acid and other gastric ferments, and since it was slightly alkaline and presented evidence of ptyalin fermentation, he concluded the material had not been in the stomach. The prognosis as to complete cure is unfavorable, although vast improvements are attained by therapeutic measures. [J.F.]

Mitral Nanism.—Under this name, Gilbert and Rathery¹ describe a dwarfed state, the result of mitral stenosis, either inherited or acquired early in life. There are pure and impure types of this mitral dwarfism. The condition expresses itself in a retardation of the growth, *e. g.*, the preservation in adult life of the anthropometric indexes of the child, and the symptoms of feminism; also the premature union of the epiphyses. Congenital anomalies, such as syndactyly, congenital amputation of the fingers and toes, accessory fingers, prognathism, fusion of the ear-lobules, malformation of the nasal cloaca, hare-lip, deformity of the sternum, and absence or deficiency of the hair, may be present. Visceral hypoplasias have also been noted. These manifest themselves in visceral dwarfism and in psychic disturbances (hysteria); also in what the authors call mitral chlorosis. Genital disturbances, such as infantilism and sterility, may also be present. At times, the thyroid is imperfect and there is an association of mitral stenosis with myxedematous infantilism. [D.R.]

Abdominal Massage in Heart Disease.—A. Neumann and F. Frick² have employed the various methods of abdominal massage in 24 individuals suffering with different cardiac and vascular lesions, to determine the behavior of the pulse and blood-pressure, and to control their subjective condition during and after the treatment; their reason for this research has been the differences of opinion expressed by different observers, and especially since some have claimed that the method is contraindicated in these diseases. In most cases the pulse became somewhat slower, while the blood-pressure remained uninfluenced or increased; sometimes a slight lowering of blood-pressure was noted. Subjectively the patients invariably felt improved. Irregular pulses became regular during the treatment. They conclude that in cardiac disease without grave disturbances of compensation, abdominal massage is permitted, and in many cases it will even be of service as regards the heart itself; in cases with high pulse-rate this will usually be lowered. Kneading and stroking in the direction of the colon will be of most service. [E.L.]

Management of Acute Nephritis: The Baccelli Method.—De Rossi³ says Baccelli emphasizes the fact that to the actual venous stasis, in the kidney, is due much of the derangement. He has practised for many years in his clinic at Rome systematic blood-letting in these cases. Pressure must be reduced. The tendency of some clinicians is to advise nephrotomy. Conservative opinion will reserve this for unilateral and localized pathologic processes; nephritis may be neither. While some may object to blood-letting because of a debilitating outcome, it should be remembered that clinical facts outweigh theoretic objections. A case is reported by the writer which illustrates his teaching. It is noted that improvement advanced, albumin rapidly disappeared, and edema and other troublesome symptoms disappeared in 10 days. Baccelli insists on absolute milk diet. Later, the hydrocarbon element is cautiously added. Helays stress on the advantage of giving regular quantities of distilled water, which is a diuretic. [T.H.E.]

EDITORIAL COMMENT

The Closure of Bone Cavities.—One hardly appreciates how large a number of procedures have been tried to aid in closure of bone cavities until he looks through the literature of this subject. These varied and persistent efforts give sufficient evidence of the difficulties which have been met and show the urgent need of some efficient means for accomplishing this end. Among the different procedures which have been tried are: Closure under blood clot, as suggested by Schede, a procedure which has not proved very successful in the majority of cases; direct transplantation of human bone, which it is usually very difficult to obtain, but this succeeded with Ollier, and has been tried by a few others; insertion of bone from animals, either removed entirely or allowed to grow in place before being detached, as was done by Morton,¹ of San Francisco, who successfully grafted the ulna of a living dog into a defect caused by a compound fracture. All of these methods are so difficult to carry out that they have not come into general use. The insertion of aseptic materials, such as aluminum, celluloid, or guttapercha into bone cavities, has been tried by many surgeons, but these materials usually act as a foreign body, causing necrosis and suppuration, which necessitates removal. Successes with absorbable material, such as catgut, sponge, and decalcified bone, have not been numerous. The latest attempt of this kind which we have noticed is by Fantino and Valan,² who report a series of operations carried out during the past 3 years, in which they have used ground decalcified bone mixed into a paste with thymol and iodoform. They found that it was possible to use decalcified bone alone in aseptic cavities, but it was difficult to fill the cavity entirely, and if blood accumulates, it is easily decomposed and gives rise to failure. After trying different ways of rendering bone cavities aseptic, they have now adopted the method of filling with 10% iodoform and glycerin emulsion, and they develop iodoform vapor by heating the emulsion in the bone cavity with the red-hot blade of a thermocautery. They find that the high temperature produced in this way does not give unfavorable results. The thymol and iodoform were chosen after considerable experimentation, because it was found that while they make a fluid mass at 75° C., when mixed in proportion of 1 to 2, this mass hardens at 60° C., which prevents it from being absorbed and causing symptoms of poisoning. Histologic study of sections from animals shows that this mass is penetrated by connective-tissue fibers in which bone salts are rapidly deposited. Very little of the mass is found after 6 months. Because of its antiseptic properties this mass can be used in cavities that are not entirely aseptic. The transformation of the mass into new bone tissue was found complete in from 3 to 8 months. Brief histories are given of 30 patients in whom this material was used for filling and closing bone cavities with favorable results. The large number of cases in which the originators of this method have used it successfully seem to give promise that it will prove a greater help in the closure of bone cavities than many of the other methods which have been tried. The fault of all of these methods has been, either that they have been extremely difficult to carry out, or limited in applicability to comparatively few cases, or that they have not given very satisfactory results. It has not been a very difficult matter to close bone defects in cases in which no serious disease existed, but in cases in which there is a suppurative process it is a decidedly different matter. This method seems to have the advantage of

simplicity and applicability in suppurative cases, and the large number of favorable results reported by its originators certainly entitles it to a trial by other surgeons.

REVIEW OF LITERATURE

Modern Ether Narcosis.—C. Hoffman¹ recommends the Witzel drop method of giving ether; it combines the unlimited admission of atmospheric air during the narcosis, the amount of ether necessary is kept at as low a level as possible and where it is insufficient to produce narcosis, adjuvant measures such as morphin and chloroform are permitted. These substances, however, do not constitute the narcotizing elements, but are only, as he states, adjuvants to the production of the anesthesia. He also lauds the drop method because of its simple technique; anyone knowing how to administer chloroform can etherize by this method, especially as it does not require the same painstaking care. He feels certain that ether will displace chloroform from its throne as anesthetic of the future. [E.L.]

The Surgical Treatment of Chronic Ulcerative Colitis.—Nehrkorn² says two objects are desired: (1) The affected intestine should be kept at rest and free from feces; (2) local treatment should be applied to the ulcerated and inflamed mucosa. He does not favor primary intestinal anastomosis. The production of a fistula not only is a much simpler operation, but also affords opportunities for local treatment. The operation can be done upon greatly exhausted patients, and without an anesthetic. Nehrkorn says the stool is nearer the normal at the sigmoid than at the cecum, and since it has been shown that local treatment can be applied just as efficiently at this point as at the cecum, he urges that the colostomy be done at the sigmoid. For local treatment he uses either camomile tea or a weak alcoholic solution of salicylic acid. [J.F.]

Tuberculous Ulcer of the Rectum.—D. P. Mayhew³ says that the diagnosis of these ulcers rests on vision. For examining the lower 3 inches of the rectum he prefers the ordinary nonfenestrated bivalve, aided by a laryngoscopic mirror. Unless the ulcer be very large it can thus be seen plainly throughout its entire extent which cannot always be done with the proctoscope. A method of treatment that has given entire satisfaction in several cases is the following: The ulcer is painted with a saturated solution of trichloroacetic acid. This is repeated the next day and after waiting a few minutes for the acid to act, the pellicle of destroyed tissue is removed with a curet. The treatment is repeated, if necessary, until the fibrous floor of the ulcer is reached. The cleaned ulcer is then dusted with one of the iodine-containing powders. At each dressing the ulcer is washed with Lugol's solution and the powder again applied. Whenever the ulcer looks unhealthy and the granulations show signs of breaking down the acid and curet should again be used. The rectal mucosa should be treated with irrigations of krameria and protargol. [A.G.E.]

Experimental Investigations Concerning Decapsulation of the Kidney.—B. Asakura⁴ finds that unilateral decapsulation of the kidney in animals may be performed without any noticeable injury. A new capsule is formed, accompanied by the development of a collateral circulation between the kidney and the abdominal wall. This process entails no harmful influence on the kidney substance. The writer produced acute purulent inflammation of the kidney in animals, and then tried the effects of decapsulation; the results were entirely negative. Decapsulation seemed to exert a favorable influence on infections produced subsequent to the operation. Bilateral decapsulation seems to be borne almost as well as the unilateral operation. The results in man, as reported by Edebohl, have been very favorable and promising. [B.K.]

Kocher's Osteoplastic Resection of both Upper Maxillas.—Payr⁵ after reporting a case of cavernous fibroma of the superior maxillary bones which he removed by Kocher's operation, discusses the various procedures practised in the removal

¹ Münchener medicinische Wochenschrift, 1, No. 46, 1903.

³ Colorado Medicine, February, 1904.

⁴ Mitth. a. d. Grenzgeb. d. Med. und Chir., Bd. xii, p. 602.

⁵ Archiv für klinische Chirurgie, 1904, lxxii, 284.

¹ American Medicine, 1902, Vol. iv, p. 55.

² Archiv für klinische Chirurgie, 1903, Vol. lxx, p. 730.

of such tumors. He considers that Kocher's method of osteoplastic resection of both maxillary bones offers a better view of the nasopharyngeal space than any of the operations practised. It guarantees the complete removal of the tumor. In simple fibroma he advises less dangerous methods at first. The technic is not more difficult; the method does not disfigure nor is the function of the parts operated upon disturbed. Although the operation is grave, all cases thus far operated on have recovered. Preliminary tracheotomy and preventive ligation of both external carotids are made unnecessary by the Trendelenburg position. [E.L.]

Hemorrhoids in Children.—Reinbach,¹ reports four cases, the first of which was in a child of 14 years, the second in a child of seven weeks and the third was three and one-half years old, and the last a boy of eight years. The child of seven weeks was not only born with the hemorrhoids but had contractures of the three middle fingers, changes in the phalangeal joints, the chin was drawn back, right-sided congenital dislocation of the hip and pes planus. In the first case he effects a cure by carbolic injections and in the third case he did a Whitehead-Mikulicz operation. The pieces he took for microscopic examination were in the majority of instances made up of spaces filled with blood; the walls were composed of fibrous tissue which at times contained some elastic tissue at other times a small amount of smooth muscle tissue. He says the picture is essentially that of a newgrowth. Reinbach says the theory that obstruction in the liver produces hemorrhoids fails when we consider that the inferior hemorrhoidal veins concerned in the production of external hemorrhoids and the middle hemorrhoidal veins concerned in the production of the internal hemorrhoidal are both tributaries of the internal iliac veins. He is not inclined to the view that hemorrhoids are due to accumulated fecal masses, since in many of the cases there is no history of even sluggishness of the bowels. The occurrence of hemorrhoids in children is a very important fact in this connection. He is strongly of the opinion that hemorrhoids are essentially newgrowths. [J.F.]

Pancreatic Cyst and Extirpation.—Andreoli² considers occlusion of the duct most commonly the cause of cyst, but refers to more obscure reasons which may be causative. He believes calculus, as lithiasis elsewhere, is parasitic in origin. Difficult as diagnosis may be, once the laparotomy is done, a pancreatectomy is indicated; partial interference is not satisfactory, but when adhesions, or extensions of morbid processes, forbid, may be enforced; and mere tapping the cyst will be reserved to such cases as are absolutely inoperable. [T.H.E.]

Treatment of Fractures.—J. P. Warbasse³ says the unsatisfactory results in the treatment of fractures, which still occur in the hands of the most careful and experienced, are usually attributable to one or both of two things—too great deference to the whims and present comfort of the patient, and a division of the responsibility by the two or more surgeons in attendance. In a young or healthy person the securing of a perfect mechanical result is the prime object and the opinions and pleasures, even the personal comfort, of the patient should all give way to this end. One surgeon should hold himself responsible for the result, no matter how much counsel he may call in; the full treatment must be in his hands. Nothing but harm will come from the violation of this rule. An apparent persistence of callus, except in cases of imperfect immobilization, should suggest the presence of overriding or of osteosarcoma. Warbasse believes that there is too much tendency to cling to the traditions in the treatment of fractures. Advance in the surgery of fractures has not kept pace with that of the abdomen and brain. A fracture complicated by irreducible displacement, or pressure or injury to a nerve trunk, should be given the advantages which surgery can now offer. [A.G.E.]

Acute Intestinal Invagination in Childhood.—L. Kredel⁴ has observed 12 cases, in 9 of which operation was performed. Shock is the greatest source of danger in young children. In order to avoid this, it is necessary to operate early, within the first 24 hours, especially in infants. Injections of

water or inflation with air should not be performed in children under 2 years, except as preparation for operation. If the invagination is found to be irreducible at operation, the prognosis is very unfavorable, and it becomes necessary to adopt operative measures that are as conservative as possible. In many cases the establishment of a temporary artificial anus is all that can be done. [B.K.]

Perityphilitis, Peritonitis, Meteorism.—A. Oppenheim¹ calls attention to the fact that an abscess in the region of the appendix or pelvis may remain in a latent state, sometimes for three years. As a result of a slight trauma it may become active and give rise to a purulent peritonitis. Since the pus in the abdomen in his case was odorless, he concludes the peritonitis was secondary to a latent abscess. When the peritonitis is due to a perforation of the intestine, various bacteria enter and produce a penetrating odor. He says if meteorism exists for any length of time it produces paralysis of the splanchnic nerves with a resulting dilation of the mesenteric vessels, consequently a weak rapid pulse, such as is seen in hemorrhage. [J.F.]

Contribution to Functional Kidney Diagnosis.—R. Goebell² publishes the results of the various functional kidney tests from 7 cases of different varieties of renal disease. They were not as invariably accurate as have been reported by others. He was able to determine by combining the various methods which kidney was the more diseased, but he found it impossible to be certain, whether in case one kidney was removed, the other would be sufficiently well to carry on the work by itself. The freezing-point of the blood was rarely the same in 2 examinations; and when the same, it was not necessarily to be trusted; had he depended upon it alone erroneous deductions would have been drawn from the findings. In one case the freezing-point was -0.60° . The left kidney was removed in spite of that and the patient recovered. In another case, left-sided tuberculosis and right-sided pyelitis, the freezing-point was 0.565° . The left kidney was removed and the patient became uremic, remaining so for 5 days, but recovered ultimately. The phloridzin method was found absolutely unreliable. Even though the results of the various tests are not reliable, Goebell does not think that they should be discarded, especially as, if certain precautions, which have been followed by him lately, are observed, their results can be made much more trustworthy. The patient should be kept on a test diet for several days prior to the examination; urine should be taken from both kidneys by ureteral catheterization a definite period after a meal; the catheter should be permitted to remain in place for several hours and urine taken at definite intervals should be examined; the amount of urine passed during these periods from the 2 kidneys and its molecular concentration should be noted. These conditions should be obeyed, because surgically diseased kidneys cannot work equally and regularly, as neither the relation between the freezing-point nor the molecular concentration of the urine of the 2 kidneys is constant, and because this relation cannot enlighten us absolutely regarding the functioning ability of the 2 kidneys. [E.L.]

GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

EDITORIAL COMMENT

The Diagnosis of Primary Carcinoma of the Vagina.—Primary carcinoma of the vagina, as usually seen, will represent a circumscribed neoplasm, and only rarely comes under the observation of the surgeon at the period when it simply forms a cauliflower growth situated in the vaginal walls. When the patient seeks advice for the first time, it is usually with a broken-down ulcer, with a crater-like aspect, with a tendency to involve the underlying structures and presenting an infiltrated base. In other cases the affection may be met with under the form of a diffused neoplasm involv-

ing almost the entire vaginal surface, which changes the canal into a rigid, unyielding tube. In both forms the lymph-nodes are secondarily involved at an early date. The symptoms observed in the early stages are the same as those met with in carcinoma of the cervix. The disease, which in the beginning is superficially seated, bleeds easily from the slightest touch, especially during coitus, and for this reason this symptom must be considered as one of the most important. Unfortunately, like in carcinoma of the cervix, it appears in many cases at a comparatively late date in the development of the affection. In patients who are cleanly and who observe themselves carefully, a changed condition of the vaginal secretions will be noted. A more or less disagreeable odor will be remarked, which will always draw the patient's attention to her genital organs. Unfortunately for the surgeon, the presence of suppuration or ulceration within the vagina are the conditions which lead the patient to seek the advice of her physician, and which indicate that the malignant affection is already advanced. Since the connective tissue of the pelvis is involved rather early in the course of the disease, symptoms of general cachexia are met with at a rather early period. Added to these, other phenomena occur which indicate that the neoplasm has involved other organs, such as the rectum, and, in rare cases, the bladder, when the disease starts in the anterior vaginal wall. We then find these unfortunate patients afflicted with a rectovaginal fistula or a vesicovaginal fistula. There are few, if any, difficulties in making a diagnosis of vaginal carcinoma, because by digital examination the finger readily detects the growth by its peculiar uneven surface, with its tendency to break down. Then again, a more or less extensive infiltration will be discovered, involving the tissues of the neighboring structures, but it will be necessary to find out whether or not the neoplasm originated primarily in the vagina, or has extended from a uterine neoplasm. It is quite important to differentiate a carcinomatous growth of the vagina from a syphilitic or tuberculous lesion. In both of these affections we find a similar breaking down and extension into the neighboring organs, but the history of the disease and the local examination will usually clear up all doubts as to the true nature of the disease. Primary tuberculosis of the vagina is extremely rare, and usually is only present when tuberculosis of the vulva or uterus is manifest. A microscopic examination should certainly render the diagnosis evident. The prognosis of vaginal carcinoma is the same as in any other malignant affection, namely, very poor, and it is only by an early, radical interference that it can be improved on.

REVIEW OF LITERATURE

Abdominal Hysterectomy in Carcinoma.—Pettazzi¹ admits the rationality of this, theoretically, but claims from experience that success is not certain. When possible, he limits the operation to selected cases. The vaginal route is advisable, if the lesion permits. His experience in laparotomies has enabled him to observe the frequency of shock following abdominal interference. He believes the abdominal cavity may be infected during laparotomy; cases of recurrent cancer are due to this very much more often than admitted. He exercises a narrower selection than Makenrodt's formula might render operable, for the reason that his results have been unsatisfactory in diffuse cases. [T.H.E.]

Tuberculosis of the Urinary System in Women.—G. L. Hunner² reports 35 cases occurring in the service of Dr. Kelly and his assistants at the Johns Hopkins Hospital. The right kidney was operated upon in 17, the left in 18 instances. The paper deals mainly with the question of diagnosis. Hunner believes that by far the larger number of cases of urinary tuber-

culosis in women begins in the kidney; he classes only 5 of the 35 cases as primary bladder infection, and says that in the past 6 years he has seen only 2 cases of tuberculosis of the bladder in which other portions of the urinary system were intact. While the ability to do cystoscopic work is of very great help in the diagnosis and treatment of this condition, inability to use that instrument does not excuse the physician from making the diagnosis. Tubercle bacilli should be found in practically every case; do not examine 20 or 30 slides in one day but 2 or 3 slides daily for a week or more. Hunner severely denounces what he calls the abuse of cystoscopy. This consists principally in catheterizing supposedly healthy kidneys through bladders known to be infected or a supposedly sound organ when the opposite one is diseased. The writer is sceptical regarding the topical treatment of bladder tuberculosis; he has never seen a patient recover without operation. [A.G.E.]

The Clinical Importance of Retroflexio Uteri.—G. Winter's³ researches have shown that of 710 apparently normal women 154 had retroflexed uteri; of these 154 women, 90 (60%) complained absolutely of no gynecologic symptoms. A closer examination of the symptoms complained of by women with this condition revealed that in nearly all cases the symptoms are due to some coexisting complication. Of 90 women with retroflexion complaining of symptoms which were at first believed to be due to the retroflexion 88 were found to have a complicating condition: 6 were pregnant, 5 had puerperal hemorrhage, 6 prolapse, 15 catarrh, 31 adnexal disease and perimetritis, 18 parametritis, and 3 had rarer complications. Upon removal of the complications the symptoms claimed to be due to the retroflexion disappeared; only in the cases of puerperal hemorrhage was it necessary to treat the retroflexion. He found further that the complications did not produce the retroflexion, nor the retroflexion the complications, even where it had existed for years, nor was it capable of producing diseases of the nervous system, as hysteria. The treatment of retroflexion therefore is the treatment of its complications. Simply to operate on a healthy woman because she has retroflexion is absolutely uncalled for. [E.L.]

Surgery for Inoperable Uterine Cancer.—R. S. Gamboa,² in an incomplete report, suggests the value of cutting down on the lesion and ligating the branches of arterial supply. Many cases so treated show improvement, and the wretched discharge is greatly lessened. One death occurred among 37 patients. When hysterectomy is impossible, and the patient will bear etherization, the writer offers the above procedure. He cannot report the outcome of all his cases, since it is difficult to trace them after leaving the clinic, but those now known are in the best condition to be hoped for, considering the lesion which, of course, remains. [T.H.E.]

Practical Lessons from Cases of Eclampsia.—Barton Cooke Hirst³ gives valuable points learned from an experience of more than 100 cases of eclampsia. He finds nothing in the clinical observation of nephritis in pregnancy to shake his belief in insufficient renal activity as a cause of eclampsia; we should hold fast to the lesson taught by experience, that nephritis in pregnancy is one of the gravest complications. Among the premonitory signs of eclampsia there is nothing comparable in value to the presence in the urine of considerable and increasing quantities of albumin. The urea excretion is valueless in comparison. A certain number of cases occurs without precedent albuminuria, but the number is much smaller than might be inferred from the reports in medical literature of sporadic cases. Hirst has finally reached the conclusion that the view that rapid evacuation of the uterus is the proper treatment for eclampsia is erroneous. He is better satisfied with treatment directed solely to the eclampsia without regard to the uterine contents, until such a degree of dilation of the os is secured spontaneously that delivery can easily be secured without violence. The use of opium is not recommended. Hirst closes by emphasizing the advantages of treating cases of eclampsia in a well-appointed hospital. [A.G.E.]

E. LINDAUER

REVIEW OF LITERATURE

Cumulative Action of Digitalis.—A. Fränkel's¹ investigations with the different members of the digitalis group were made for the purpose of determining their therapeutic and toxic doses, the duration of their action and, if possible, the cause of their peculiar cumulative effect. He found that none of the animals ever became accustomed to the drugs, and that their cumulative action is a very prominent property. The symptoms of cumulation always developed as the individual doses were increased or the period between doses diminished. Idiosyncrasy on the part of the animal was of very little importance. All the drugs belonging to the group are very slow in producing their first effect on the circulation; if but one therapeutic dose of digitoxin is given, the slowing of the pulse does not appear for at least 60 hours, with digitalinum verum the action was noted after about 24 hours, but even with strophanthin, the quickest of them all, it took four to five hours before its circulatory activity was established. Large fatal doses act quicker, but in the case of digitoxin six hours usually elapse, with strophanthin, 10 to 20 minutes. The first symptom of poisoning is invariably vomiting; this occurs before the circulatory changes are noted. Very small doses of any of the drugs may be toxic in time, and to stay within safe limits doses should be given, which even when several are counted together, will not produce physiologic results; such doses can then be given for a long time without showing cumulative action, but should the interval be shortened or the dose be increased, vomiting will quickly occur. Symptoms of poisoning were never very far off. Digitoxin is the most dangerous of them all. A dose of 0.2 mg. of digitalinum verum (one-half the lowest fatal dose) could be given for weeks, while 0.03 mg. of digitoxin (one-third the lowest fatal dose) produced poisonous symptoms after the third dose. The effects of the drug pass off very slowly; after a single dose of any of them the pulse-rate will remain below normal for over a week. The cause of the cumulative action is not due to slowness of elimination, as strophanthin, which shows the same cumulative activity as the others, is easily eliminated, being very soluble. The rapidity of the action of the drugs is on a parallel with their solubility. The cumulative action must be due to firmness with which they unite themselves to the sensitive cardiac muscle. The practical deductions from this series of observations are that it is much easier to obtain therapeutic results by the repeated administration of small doses than by the use of one or two large single doses. When these drugs are used over a period of time the occurrence of even physiologic alterations in the pulse-rate should be the sign for the withdrawal of the drug for two or three days, to see if their action is going to become more accentuated with the production of toxic symptoms. Digitoxin is not to be recommended for any therapeutic purpose, and is especially dangerous when the effects of a single dose are desired. If a prompt action is desired, strophanthin is certainly the most desirable of the agents mentioned. Although strophanthin has less tendency to produce an outbreak of toxic symptoms through its cumulative action, the frequent use of it may nevertheless lead to the occurrence of this condition. [E.L.]

Saline Infusions in the Treatment of Mental Diseases.

—W. S. Greidenberg² has employed subcutaneous saline infusions in mental diseases and recommends the method very warmly. He has seen excellent results from its use. The infusions have a sedative effect, promote sleep and appetite, are well borne, and under elementary aseptic precautions there is no danger to be feared. They are indicated chiefly in all psychoses of an infectious, toxic or autotoxic nature. Psychomotor excitement, insomnia, and anorexia call directly for saline infusions. The technic is simple and needs no description here. The ordinary physiologic saline solution (.7%) has been used, beginning with 250 cc. and going up to 1,500 cc. at a single injection. There are no serious contraindications to the

use of saline infusions, though some additional caution is appropriate in the presence of cardiac disease, chronic pulmonary affections, intracranial hyperemia, and generally in conditions rendering an increase of vascular tension undesirable. [L.J.]

Therapeutics of the Ichthyol Compounds.—James Burnet,¹ of the Royal Infirmary, Edinburgh, has heretofore called attention to the value of various ichthyol compounds. In the present paper he devotes special attention to ichthoform, a compound of ichthyol and formic aldehyd; and ichthargan, a compound of ichthyol and silver salt. He has used ichthoform as an intestinal astringent, an antiseptic, as a dusting powder, as an ingredient in ointments, and as a means of impregnating gauze. His general conclusions with reference to its use are that (1) it is one of the most efficacious antiseptics which we at present possess, more especially in cases of intestinal disease where its action is more certain and less harmful than salol and some other substances; (2) it is an excellent substitute for iodoform in all cases where the latter is indicated. It is odorless and practically nontoxic; (3) for intestinal administration it is even given in small doses, frequently repeated. As much as two drams may be given in one day if divided into small repeated doses. Ichthargan is a brownish-black, amorphous powder containing 28.7% of silver. He has had beneficial results from its employment in gonorrheal urethritis, gynecologic affections, in dermatologic practice, in affections of the nose and throat, in diseases of the eye, etc. Concerning the two drugs he believes they are of special value as antiinflammatory agents; they are trustworthy in action, and deserve to be more extensively used by the profession than has heretofore been the case. [A.B.C.]

Olive Oil in Diseases of the Stomach and Intestines.

According to P. Cohnheim,² large doses of olive oil (100 gm. to 150 gm. daily) exert a powerful curative influence in cases of gastrectasia due to pyloric spasm resulting from ulcer or fissure; also in relative stenosis with hypersecretion and pylorospasm; also in ulcer of the pylorus with or without hypersecretion. It is also of considerable palliative value in carcinomatous stenosis of the pylorus, with or without gastrectasia. The oil is best given continuously for some time, three times a day, one-half to one hour before eating; it may be introduced through a tube if necessary. Usually a wineglassful in the morning, and two tablespoonfuls at midday and in the evening, are the proper doses. The oil serves three indications; it stops the pylorospasm, diminishes friction, and supplies nutriment. It produces no ill effects. It has no effect in gastric pain of pure neurotic or hysterical origin. It acts very favorably in the pains of hyperchlorhydria and atrophic gastritis. [B.K.]

Some Therapeutic Applications of Chloretone.—D. M.

Hutton³ writes of the value of chloretone in nausea and vomiting. In the vomiting of pregnancy out of six cases treated in four it ceased to be distressing and in one in which previous pregnancies had ended in miscarriage the child was carried to full term. It is exceedingly useful in the sickness accompanying menstruation in many girls, what they call a bilious attack accompanied by nausea and retching. It prevents certain forms of seasickness. It relieves stomach pain of neurotic origin. It acts by rapidly numbing sensation in the stomach. It has a pleasant taste, produces an agreeable feeling of warmth and the slight hypnotic effect produced by 12 gr. or 15 gr. frequently aids the process of relief. [H.M.]

The Pharmacology of Veronal.—N. T. Botcheroff⁴ has made a number of experiments on dogs, frogs, and rabbits. He found that veronal paralyzes the central nervous system, small doses affecting chiefly the cerebrum. The sleep of veronal is very long, followed in the case of large dosage by weakness and depression. The number of heart-beats is seriously affected only by very large doses. In general, the author remarks that veronal is very similar to trional in its action, being free, however from the untoward effects of the latter. This freedom is due to the absence of the sulfogroup in veronal, and thus its prolonged use is safer than that of trional. [L.J.]

\$5.00 YEARLY.

"Consumption Rows" and "Lung Blocks."—According to the Charity Organization Society's most excellent *Handbook on the Prevention of Tuberculosis*, there is one block in New York city called "The Lung Block," which houses 478 human beings to the acre, or a total of nearly 4,000 for the whole block, not to mention animals. In the past nine years 265 cases of pulmonary tuberculosis have been reported from it. In Chicago it has a rival called "Consumption Row," from which 138 cases have been received at the Cook County Hospital in the last four years. Doubtless in these two cities these rows and blocks are not the only ones serving as such breeders of the disease, and just as certainly these two cities are not the only ones having such buildings. The facts bring out plainly the truth of the infectiousness of tuberculosis, and that the germs remain in the places for indefinite periods and for an indefinite number of reinfections. Either this, or that the conditions of ill-ventilation, darkness—there are said to be 350,000 persons in New York living in windowless rooms—and filth produce the disease. Unquestionably both causes cooperate. The remedy is not a scientific one, as scientific knowledge has long pointed out the way of relief. The cure is a social and largely a legal one. Such tenements and conditions must be legally abolished, and the community must take up the reform. We are our brothers' keepers.

The railway hospital car, concerning which reference was made in a recent issue of *American Medicine*, according to Dr. Fairchild (*International Journal of Surgery*, April, 1904, and *The Railway Surgeon*, February, 1904), has been already placed in use by the C. & N. W. R. R. He says the original idea of putting up such a car came from Mr. Cooper, the master car-builder of the railroad. One may feel a little regret that it did not come from a physician. The fact at least shows the excellent motive of self-interest on the part of the railway officers, and again illustrates the frequent identity of a wise selfishness and a wise humanity. Dr. Fairchild, in describing the car, says that in one end of the coach five sections were made, each having an upper and lower berth, thus accommodating ten patients. The water heater is in the center, and nearby are the surgeon's supply press, clothes closet, washstand, water closet, etc. The supplies in the surgeon's press comprise everything that may be required in emergencies, operations, etc. The

central part of the car has two tables at one side arranged similar to those in a dining car, corresponding on the opposite side is a writing desk and a seat running along parallel to the side of the car; this portion is well supplied with windows. At the other end is a cupboard and icebox, and opposite to this is a range stove. Up in the top in the cupola is placed a stretcher, also an operating table, and whenever the car is called and an accident has occurred, the table is taken down and firmly placed, one end resting on the side table running across the car, with portable legs at the other end resting on the floor.

Clinical Prejudices.—A famous physician, once, going through the hospital wards told a new patient to "put out his tongue." It was pointed, with a streak down the center. "You see here, gentlemen, an infallible sign of gastritis." "Have you any appetite?" "I could eat a horse," said the patient. "It is gastritis, nevertheless. Any thirst?" "No, no thirst." "Gastritis, notwithstanding. Any pain in your stomach?" "None at all, sir!" "Well, you see the pointed tongue, gentlemen; it is gastritis! Fifty leeches to the stomach!" The anecdote suggests many lessons, and perhaps to every reader it will recall memories of similar experiences. "Make a snap diagnosis and stick to it," was the advice of another wellknown teacher. But we are nowadays fast learning better than that—if not a better science, at least a better policy. The mystery of disease bears too heavily upon the conscience of the modern physician to permit him to judge hastily from insufficient data, and from single symptoms. The individuality of each case of disease, when closely studied, demonstrates that none is like another, and that the best rule in diagnosis and treatment is to have no rule.

"Gastritis Nevertheless!"—There are four truths which are not recognized by the *gastritis, nevertheless*, physicians. 1. Giving a disease a name does not in the least explain its origin, and of pathogenicity these men are seldom curious. If it is gastritis, that's enough. But three-fourths of the whole battle of medical science is to determine the cause of disease. 2. Supposing the disease to be caused by disease of the local organ, or to be located only in the organ, where one of the symptoms

appear, is the stupidest and commonest of blunders. 3. The treatment—"fifty leeches to the stomach"—has no physiologic relation to the real disease, and is not effective as a therapeutic measure. The patient gets well in spite of or at least regardless of the fifty leeches. 4. The fourth, and an unexpected lesson in this old morality is that whenever in olden times (and not infrequently today) the doctor could not fathom the mystery of his patient's absurdly persistent disease, he had refuge to the stomach. It was something like the method of the old piano tuners, who got rid of the dissonances of the keyboard by gathering them all in one octave, which they named "the devil." The player was to avoid this octave as much as possible. In the last century Europe turned itself largely into making dieting establishments, cookery books, health resorts, sanatoriums, etc., for the cure of "dyspepsia." And today there is no agreement, no science as to the causes of the "dyspepsias" which as much as ever afflict modern patients.

Vanity and the Persistence in Error.—"Gastritis, notwithstanding!"—said the great clinical teacher, and passed on with perfect self-satisfaction to the next patient. But he did not notice that among his pupils following him through the wards, not all were dumb with awe and admiration. There was one, at least, who tells the story. The reverence due to authority has often led the authoritative to sorry ends, even when the reverence was real and the authority meritorious. But, as all know, the reverence may be only acted, and the worshiper may smile secretly, perhaps grimly at the plight both of the false divinity and of the sceptical suppliant. There are no students more expert than the medical variety in exposing the errors and make-believes of their teachers. Every medical college rings with the laughter,—but not where the learned one can overhear! In after-life it is the same. The younger practitioners quickly penetrate the disguises of sham intellect, the pretenses of clinical insight, on the part of unwary consultants and leaders. But the sorriest part of the farce is when the "gastritis-nevertheless" professors do not suspect the real feelings of their colleagues, and do not dream that with death, the account on the slate will quickly be rubbed out. Scientific progress cannot allow individual prejudices and vanities long to block her way. How many famous physicians disappear in an instant and nothing is thereafter heard of them! It is not because they did not write or make great discoveries. It is because they taught the theory and not the practice of medicine; because preformed conceptions of disease governed their opinions rather than careful clinical observation; because they cared more for the science of disease, and for their individual idea of the science, than for the patients' single and peculiar disease; because they treated the disease rather than the patient; because, in a word, they were, *gastritis-nevertheless* physicians.

New Medical Truth.—In our time we are accustomed to think the new truth is accepted too readily—even before it is at all certain that it is true. The avid hunger for the novel, however, has little or no relation

with the discernment or the acceptance of the really progressive steps made in medical science. It would be strange indeed if the world-old law should be suddenly changed. In all times and in all kinds of discovery, woe has been to him who dares to question the accepted and to replace it by the hitherto unknown; and medical progress can scarcely be an exception to the law, although the very condition of science is openness of mind to the new view. And it is no exception. Without knowing anything of bacteriology and disease germs, guided solely by observed clinical fact, Semmelweiss had proclaimed the truth that puerperal fever was due to poisonous matter carried by the physician or accoucheur. Semmelweiss was persecuted by his medical colleagues, his views were denounced by the professional leaders, and he was turned out of his professorship and ruined. Facts, however, were upon his side. In the Paris Maternité 64 women out of 347 died, in 1856, in a few weeks, and in 1864 out of 1,350 admissions 310 died. When it came again to the acceptance or rejection of the greatest modern medical truth, the germ theory of disease, there was again shown the same "tyranny of medical education," as Dr. Roux calls it. The younger men were the first to see the truth. There is a strange fatality which makes the official spokesmen fail to speak rightly. The leaders hardly ever lead. The fact may encourage the timid to rely less on the guides who do not guide than on their own careful personal observation and independent judgment. There is doubled certainty of tragedy to the reformer, however, if the supposed truth is not true. If it does turn out to be true, the false critic is perfectly unharmed; he smiles loftily at the old battle, and from his reporting, one would never suspect that he fought on the wrong side.

The Stages of Progress in Practical Sanitation.

—In a thesis by Dr. Wm. H. Allen for the degree of Doctor of Philosophy (Seventeenth Report, Pennsylvania State Board of Health) the steps in the evolution of practical sanitation are traced as follows:

1. The period of racial tutelage, when the fundamental lessons of personal hygiene were taught by the process of natural selection.
2. The period of esthetic or comfort sanitation, street paving, sewerage, waterworks and baths.
3. Commercial sanitation, the era of quarantine protection against imported plagues, and street care in the interests of guild commerce.
4. The period of nuisance abatement and the evolution of a code to insure the leisure class against annoyance.
5. Leisure class sanitation for the protection of the upper class against the filth and disease of city slums.
6. Philanthropic sanitation in the interests of the submerged classes.

The sixth is the stage in which we now find ourselves, or are preparing to enter. But the actual difficulties encountered depend upon the lack of local interest and cooperation, and in the want of State appropriations. In 1898, only 231 out of 800 boroughs of the State had appointed local Boards of Health, and many of those appointed were inactive, and the majestic State

appropriates only \$6,000 for the expenses of the State Board! The truth is that the science of hygiene has vastly outrun the practice, and that all progress now awaits the participation of the public. "Sanitary progress depends upon society's appreciation of health, not upon technical knowledge of disease." The death-rate may be reduced one-half whenever the people and their legislators wish. There is little evidence at present of the existence of the wish.

Bovine Tuberculosis and Public Health.—The present status of this most important question is briefly set forth by D. E. Salmon in a publication¹ embodying the annual reports on the relationship between bovine and human tuberculosis made to the American Public Health Association for the years 1901, 1902, and 1903. Parts of the subject matter have been previously published in bulletins of the department and elsewhere, but the three conjoined reports form a pamphlet that is of value alike to physicians, sanitarians, and the laity. Much of the last report is occupied by a rebuttal of the postulates of Koch as announced at the British Congress on Tuberculosis. Reference is made to the work of DeSchweinitz and of Mohler, not yet published, in which two distinct lines of experiments were carried on in such manner that one might serve as a check to the other. The results were in accord in showing that a certain percentage of tubercle bacilli obtained from man were virulent for animals. These were identical in their cultural and morphologic characteristics with bovine bacilli. Comparative studies of bacilli from various sources confirm previous experiments, showing that the types of both human and bovine tubercle bacilli are very inconstant and readily change in morphology and virulence. The results of the German tuberculosis commission, as shown by the preliminary announcement of Kossel, tend to support these findings. From the work done during the past two or three years it now appears to be demonstrated without a doubt that bovine tuberculosis is communicable to man. The proportion of human cases to be attributed to this source still remains to be determined.

Sleeping-sickness in Uganda.—An exceedingly interesting pamphlet of 87 pages is that containing the "Further Report on Sleeping-sickness in Uganda," by Bruce, Nabarro, and Greig.² The main conclusions arrived at in this report were published some time since in the British journals, but many suggestive data are now supplied. Briefly, the authors consider it proved that sleeping-sickness is caused by the entrance into the blood and cerebrospinal fluid of a species of trypanosoma, probably the species discovered by Forde and described by Dutton as *Trypanosoma Gambiense*; that the trypanosomes are transmitted only by a species of tsetse fly, *Glossina palpalis*; that sleeping-sickness is, in short, a human tsetse fly disease. It must be said that the results of their investigations and animal experimentations as set forth in the report appear fully to justify

the above conclusions, and thus render it reasonably certain that the etiology of one more hitherto obscure disease has been definitely settled. The various steps in the working out of this problem form one of the most fascinating chapters in the history of modern investigative medicine. Incidentally another member of the protozoa, long known as infesting the lower animals, has been added to the list of blood parasites in man. An important question, one that we may hope to see solved in the near future, is that raised by the statement in the report that the so-called cases of trypanosoma fever may be, and probably are, cases of sleeping-sickness in the earliest stages.

The Weather and Pneumonia.—There seems to be a difference in the rate of increase of the mortality from pneumonia in different parts of the country which is very puzzling. But still more noteworthy is the difference of conclusion as to the agency of weather. The last report of the Indiana State Board of Health is of value in giving the comparative mortality in an entire State due to the disease for several years, and especially as this is a large inland State of the Middle West. The increase is clear. These are the figures:

PNEUMONIA DEATHS BY MONTHS FOR FOUR YEARS.

	1900.	1901.	1902.	1903.	1904.
January.....	385	622	427	410	540
February.....	401	608	512	399	711
March.....	594	603	470	402
April.....	463	404	352	317
May.....	224	250	192	209
June.....	102	101	83	124
July.....	63	53	60	77
August.....	54	63	62	79
September.....	61	73	112	110
October.....	136	129	157	132
November.....	191	206	181	241
December.....	299	380	267	392

After comparing the weather conditions during the winter months of greatest mortality, the *Bulletin* concludes that the weather had no influence whatever in changing the mortality rate. There is a falling back upon the mystery of "an infection of unusual virulence and in unusual quantity."

Röntgen Rays in the Dublin Law Courts.—The surgical possibilities and the legal liabilities of the use of the röntgen rays were—for the first time within the British dominions—exhaustively investigated in the Dublin Law Courts last month. A lad, resident in Galway, the seat of one of the "Queen's Colleges," was suspected of having a needle lying within or near one of his knee-joints. Professor Colohan (of Queen's College) sent him to the assistant in the physical laboratory, a man named Haire, to have the joint skiaographed—in order to perfect the diagnosis. The result was not satisfactory, and after some repetition a röntgen-ray burn appears to have been developed. Ultimately the boy was sent to Dublin for advice and treatment, and the comments there made on the origin of the cutaneous sore led to the legal proceedings. There were three actions brought by the guardians of the boy—one against Dr. Colohan; one against the laboratory assistant, Haire; and one against the college authorities.

¹ Bulletin No. 53, Bureau of Animal Industry, U. S. Depart. of Agriculture.

² Royal Society: Reports of the Sleeping-sickness Commission, No. 4, 1903.

The trial lasted seven days; twelve K. C.'s were retained throughout; the most noted experts were summoned from the other side of the Irish channel; and those of Dublin were necessarily pressed to the front. The evidence of Dr. W. S. Haughton, the premier röntgen ray specialist of Dublin was the conspicuous expert feature of the whole trial. Every possible aspect and every practical property of the röntgen rays, in their relationships with human tissues, were thoroughly thrashed out in open court, and the most up-to-date röntgen ray machinery was made to display its modes of action to the jury. After the brilliant display of native science and native wit, nobody was surprised that the röntgen ray specialists carried the opinions of the jury, and that a verdict was recorded in favor of the defendants. The result must have taught something to the lawyers, as well as to the general medical and lay public for the trial was one of the most expensive that has taken place in Dublin for a long period, and the plaintiffs do not appear to be persons of any substance.

The Verdict.—Judge Gibson's charge to the jury occupied about three hours, and at the close he submitted the following series of questions for their consideration. Their perusal will well repay attention. We subjoin thereto the answers which were given by the unanimous decision of the jurors, after a conference of one hour:

1. Were the Queen's College, Galway, and Haire, or one, or which of them, employed for reward to photograph by röntgen rays in December, 1902, and in April, 1903? Haire was so employed. College was not.
2. Was the sore caused by the rays? Yes.
3. Were the rays negligently applied as regards:
 - (a) Distance? No.
 - (b) Duration of such exposure? No.
 - (c) Consecutive multiplication of exposures? No.
 - (d) The type of machine? No.
4. Was the sore caused by the operation
 - (a) Of December 15? Cannot say which.
 - (b) Of December 26 and 27? Cannot say which.
 - (c) Aggravated by those in April? No.
5. (a) Did the operation of Dr. Colohan, for which Haire is not responsible, contribute to the sore? Yes.
- (b) Did the operations of Haire, for which Dr. Colohan is not responsible, so contribute? Yes.
6. (a) Was Haire negligent in applying the rays? No.
- (b) Was Dr. Colohan negligent in applying or superintending? No.
7. Before the rays were applied in April was:
 - (a) Dr. Colohan negligent in not diagnosing the sore as caused by röntgen rays? No.
 - (b) Was Haire so negligent? No.
8. (a) Was Dr. Colohan negligent in applying the rays in April after the sore appeared? No.
- (b) Was Haire so negligent? No.
9. To what damage, if any, is the plaintiff entitled? None.
10. Is any, and what amount of such damages attributable to acts of Dr. Colohan only? Not answered.
- (b) Is any, and what amount thereof attributable to acts of Haire only? Not answered.

Vacancies in the Medical Department of the U. S. Army.—There are 20 vacancies in the junior grade of the Army medical department, and candidates for the places will be examined beginning April 18. A second class of candidates will be examined on May 2. There will be two boards of examination this year. One will convene in Washington and the other in San Francisco, where there are a number of candidates.

BOOK REVIEWS

A System of Physiologic Therapeutics. A Practical Exposition of the Methods, other than Drug-giving, Useful for the Prevention of Disease and in the Treatment of the Sick.—Edited by SOLOMON SOLIS COHEN, A.M., M.D. Vol. VIII: **Rest, Mental Therapeutics, and Suggestion.**—By FRANCIS X. DERCUM, M.D., Ph.D. P. Blakiston's Son & Co., Philadelphia, 1904. Eleven volumes, \$27.50.

The title of this volume suggests that in many respects it must have been one of the most difficult to prepare—since the subjects of which it treats so nearly approach, in fact have cunningly been made part and parcel of charlatanism, that the sifting of the wheat from the chaff required the exercise of a nice discrimination; and yet, gauged by the result, the efforts of the author and the editor could scarcely have been more successful. Part I comprises an account of the functions and results of rest, and of the nature of, and the application of rest in, such diversified though commonly confused disorders of the nervous system as neurasthenia (the fatigue neurosis), the different spurious forms of neurasthenia (which the author speaks of as the neurasthenoid state and symptomatic neurasthenia), hysteria, hypochondria, chorea and other functional nervous disorders, and certain organic nervous disorders. Although, as is eminently proper, special attention is given to the remedial applications of rest, to an exposition of that systematic method of cure known as the "Rest Cure," the exigencies of the situation demanded a somewhat detailed discussion of the nature and diagnosis of neurasthenia, hysteria, hypochondria, etc. This is most praiseworthy, and its study is commended to the large body of practitioners whose conception of these states is rather hazy and who but too frequently use the terms hysteria, neurasthenia, and hypochondria, almost if not quite interchangeably, entirely forgetting that each is a readily differentiable clinical entity. Part II comprises an account of the therapeutics of mental diseases, in which are discussed the prevention of insanity, the general principles underlying the treatment of the insane, details of asylum management, and the treatment of special forms of mental disease, such as delirium, confusion, and stupor; melancholia, mania, and circular insanity; paranoia; the neurasthenic insanities; simple dementia; paresis; drug habits; and the insanities of intoxication. This is especially valuable from a practical point of view, since there is little doubt that if the suggestions embodied in the chapter were more generally carried out there would be less insanity, less crime due to insane states, and more cures in the cases curable in the early stages of the insanity. Part III deals with suggestion, with the influence of the mind upon the causation, course, and cure of disease. This, which includes a discussion of suggestion by mystic and religious methods, suggestion under artificially induced hysteria—hypnotism, pythonism, shamanism, magnetism, mesmerism, metallotherapy, Perkin's tractors, mind cure, faith cure, eddyism, etc., though brief is one of the sanest, and withal one of the most valuable and interesting chapters on the subject that we have read. The author points out and clearly shows that the underlying principle of the different faith cures—using the term in the wide sense—is the inducing of an abnormal mental state which he believes to be identical with hysteria. As a volume it is practical and valuable; it well exemplifies and fittingly reflects physiologic therapeutics in its widest sense, and it is by no means the least interesting of its healthy family.

Blood Immunity and Blood Relationship.—By GEORGE H. F. NUTTALL, M.A., M.D., Ph.D., including Original Researches by G. S. GRAHAM-SMITH, M.A., M.B., D.P.H. (Camb.), and T. S. P. STRANGEWAYS, M.A., M.R.C.S. The University Press, Cambridge, 1904.

The book is a most welcome addition to medical literature, as well as to biologic and anthropologic literature, since it is the first embodiment of the practical results of the recent work upon the interreactions of various bloods. Part I, reviews concisely the antibodies in general, and the antibodies other than the precipitins, and is a succinct review of our present knowledge of the various phenomena exhibited by normal and immune serums. Part II, takes up the main field

covered by the book—the description of everything which pertains to the precipitin test, both in the general biologic problem of the relation of species, and in the specific medicolegal problem of the recognition of bloods. The attention to detail, and the thorough treatment given every phase of the subject, make this part of Nuttall's book an ideal textbook for the biologist, and particularly for the medicolegal expert; the criminal lawyer would also find much food for thought. Part II is subdivided into a discussion of methods, of the nature of the precipitin reactions, and of the specificity of precipitins, beside other chapters of theoretic interest. Nuttall's own work concludes with a summary, and a tabulated analysis of the results obtained from 16,000 precipitin tests on 900 specimens of blood. Section VII, by Nuttall and Strangeways, takes up the question of quantitative precipitin tests. The conclusion from 500 quantitative tests is that this method excludes the personal equation which must interfere more or less in the qualitative method, but that the results of the simpler qualitative method are practically accurate. Section VIII, by Graham-Smith, discusses the bearing of 2,500 tests with precipitating antisera on the question of the relationship among the lower vertebrates and arthropods. Section IX, "On the practical application of the precipitin reactions in legal medicine," covers the application of the antisera to the identification of bloods and bloodstains, the examination of meats, of bones, of certain commercial preparations, and to the study of urine. The exceptional quality of Nuttall's book is due to two facts; it not only contains the results obtained by a master workman, but also a complete record of the work of others, the appended bibliography covering 15 pages.

Preventive Medicine.—Published by the Maltine Company, Brooklyn, N. Y.

Under this title the Maltine Company has printed the prize essays of Drs. W. Wayne Babcock and Lewis S. Somers, which were published in the *Brooklyn Medical Journal* and the *Medical News*, respectively. It is a paper covered book of some 280 pages for gratuitous distribution to the medical profession. It is well printed, contains but few advertisements, and the essays will repay careful reading.

Acute Poisoning.—Published by Victor Koechl and Company, New York City.

This is a chart about 25x29 inches in size, giving a list of poisons, their classification and varieties, chemic and physiologic antidotes, fatal doses, simple tests, and brief remarks on treatment. It makes a very convenient reference list for physicians, and would also be of value to the laity in cases of poisoning.

BOOKS RECEIVED.

[Prompt acknowledgment of books received will be made in this column, and from time to time critical reviews will be made of those of interest to our readers.]

Commoner Diseases of the Eye: How to Detect and How to Treat Them.—By CASEY A. WOOD, C.M., M.D., D.C.L., Professor of Clinical Ophthalmology in the University of Illinois, etc.; and THOMAS A. WOODRUFF, M.D., C.M., L.R.C.P., Professor of Ophthalmology in the Chicago Post-Graduate Medical School, Chicago, etc. With 250 illustrations, 7 colored plates, 500 pp. Bound in green buckram, gold side-title and top; \$1.75 net. G. P. Engelhard & Co., Chicago, 1904.

The International Medical Annual: A Year Book of Treatment and Practitioners Index. 1904. Twenty-second year. E. B. Treat & Co., New York City. Price \$3.00.

Treatise on Diseases of the Skin: For the use of Advanced Students and Practitioners.—By HENRY W. STELWAGON, M.D., Ph.D., Clinical Professor of Dermatology in the Jefferson Medical College and Woman's Medical College, Philadelphia; Dermatologist to the Howard and Philadelphia Hospitals; Member of the American Dermatological Association; Associate Member of the French Society of Dermatology and Syphilography and of the Italian Society of Dermatology and Syphilography. Third edition. With 220 illustrations in the text, and 26 full-page lithographic and half-tone plates. W. B. Saunders & Co., Philadelphia, New York, London, 1904.

Manual of Clinical Microscopy and Chemistry: Prepared for the Use of Students and Practitioners of Medicine.—By DR. HERMANN LENHARTZ, Professor of Medicine and Director of Hospital at Hamburg, etc. Authorized Translation from the Fourth and Last German Edition, with Notes and Additions, by HENRY T. BROOKS, M.D., Professor of Histology and Pathology at the New York Post-Graduate Medical School and Hospital; Member of the New York Academy of Medicine, etc. With 148 illustrations in the text and 9 colored plates. Bound in extra cloth. Price, \$3.00 net. F. A. Davis Company, Publishers, Philadelphia, Pa.

Transactions of the American Climatological Association for the year 1903. Vol. xix. Printed for the Association, Philadelphia, 1903.

Bulletin of Iowa Institutions (Under Board of Control.) Published quarterly. Vol. v, 1903. Franklin Printing Co., Des Moines, 1904.

AMERICAN NEWS AND NOTES

GENERAL.

Knife Blade in Brain for 20 Years.—News from New Haven, Conn., states that a portion of a long, thin knife blade, which had remained embedded in the skull and projected an inch into the brain of a negro, was recently removed by a surgeon. The patient is 57 years of age, and 20 years ago, in a quarrel, was struck on the head with a knife, the blade breaking off, where it had remained without producing symptoms until very recently, when the patient began to have convulsions. These increased in frequency and led him to seek medical relief, with the above result.

Miscellaneous.—**Springfield Ill.:** H. C. Fairbrother, of East St. Louis, has been appointed a member of the Illinois State Board of Commissioners of Public Charities.—**New York:** Ernest J. Lederle, until recently Health Commissioner in New York City, has established a laboratory for sanitary, chemic, and bacteriologic investigations.—**Philadelphia:** The trustees of Frankford Hospital recently elected the following physicians to membership on the visiting staff of physicians: W. H. Morrison, C. M. Nassau, S. K. Bolton, E. E. Keiser, and George C. Hanna. Dr. James K. Young has been elected assistant professor of orthopedic surgery in the University of Pennsylvania.

Bequests to Charity.—The children of the late Mayer Lehman, who, for 19 years, was director of Mt. Sinai Hospital, have given \$93,000 for the construction of a complete dispensary building which is to be dedicated in memory of their father. By the will of Herman Weiller, \$500 each is left to the Jewish Hospital Association and the Jewish Foster Home of Philadelphia. By the will of Mary M. Johnson, of Philadelphia, who died in 1884, about \$150,000 was left to various charitable institutions, mostly of Philadelphia. The funds have but lately become available. By the will of Julia F. H. Nevins, who recently died in New York, \$1,000,000 was left to establish a home for aged incurables. Provision is to be made for 100 people in the home.

Treatment of Children.—From *Charities* we quote the following: The seventieth annual report of the Boston Children's Friend Society is of peculiar interest. The society, one of the oldest children's institutions and child-saving agencies in the country, has, within the past few years, changed from the institutional to the placing-out system, an unusually radical change for a conservative institution. Referring to this, the board of directors says: "From time to time the question is asked if the new method of placing the children in homes is the best way of helping them? We, as directors, say yes, and the opportunities which we have of judging prove to us that in no other way could the child be given such a chance for development."

Increase in the Price of Quinin.—Quinin, which was advanced February 16 to the extent of 2 cents an ounce, is likely to go still higher, in the opinion of some men in the trade, while others do not look for any further advance. A report has been circulated that the Russian Government is negotiating in European centers for large supplies for its army and navy. A representative of a prominent New York firm has stated that war is not likely to have any immediate effect upon prices of quinin. The soldiers now in the field, for the most part, were in military service before hostilities began, and were consumers of drugs. The exposure of men to campaign hardships may call for the use of somewhat larger quantities of the drug, but this additional amount will have little influence on the market.

The House, its History and Influence in Hygienic Progress.—This the title of a lantern lecture which under certain conditions will be given, gratis, by Dr. George M. Gould. It is designed to interest a lay audience and to render aid in sanitary house-building and housekeeping, in tenement house reform, and in the warfare against ill ventilation, and the diseases, tuberculosis, etc., which according to modern scientific conclusions are dependent upon unhygienic houses and house life. It is illustrated by about 100 lantern slides. Preference will be given to invitations of medical societies under the auspices of which the public meeting should be held. The local expenses for the hall, lantern, etc., are to be arranged for and paid by the local committee. The lecture was given at Atlantic City by invitation of the Atlantic City Medical Society, April 14.

Open-air Hospitals for the Tuberculous in the Naval Service.—An exchange states that Surgeon-General P. M. Rixey, of the Navy, finds it necessary to visit the naval station at Port Royal, S. C., before he submits to the Navy Department his detailed plan for an open-air hospital for the tuberculous in the naval service. In this plan of the surgeon-general to establish such a camp at Port Royal he has the support of the officers of his corps and the experts in the treatment of tuberculosis outside the service. The neighborhood has for many years been regarded as a health resort, and it is believed that no better use could be made of the abandoned naval reservation at Port Royal than to convert it into such an institution as is recommended by the surgeon-general. That officer will make a visit of inspection to Port Royal within the next few weeks, just as soon as his official duties permit him to leave Washington.

Proper Ethics of the Newspaper.—A correspondent writes to *American Medicine* that he recently wrote a private communication to one of the editors of the *Montreal Daily Witness*, asking the question "are you aware that Peruna advertised in your paper has been analyzed and found to contain about 50% of bad whisky? I ask this knowing your interest in the cause of temperance." The correspondent writes that his question was answered in a practical and satisfactory manner and further and better than the Peruna advertisement, which was an extensive one, was promptly omitted in the further issues of the *Daily Witness*. He concludes by saying "such an instance of consistent and conscientious action on the part of a newspaper should, I think, receive some word of commendation from the profession, and I should feel personally grateful to see, in an early issue of *American Medicine*, a short notice of the above facts."

Panama Commission Sails.—The Panama Canal Commission, accompanied by a number of engineers and contractors has departed for the Isthmus. Accompanying them were Colonel William C. Gorgas and Dr. Louis LaGarde, of the United States Army, and Dr. Ross, of the Navy. These men are all experts in tropical diseases, and their duty will be to find the necessary means of making the Isthmus sanitary. A correspondent, more humorous than truthful perhaps, states that in some way it became noised abroad that the government is prepared to pay large rewards to the scientist or inventor who can exterminate the bugs that infest the Panama Canal strip, and there were at least 40 bugkillers on the *Alliance*, which sailed for Colon. If variety and oddity of apparatus and the smell of chemicals can kill the bugs on the Isthmus, the party which sailed will surely be successful. They carried all kinds of sprays, explosives and bug foods, and each man had a complete library of books dealing with his subject. One tall, lean fellow, with blond hair that hung in ringlets on his shoulders, exhibited a revolver by the explosion of which a chemist dust was liberated which floated through the air, and was guaranteed to kill all bugs within a radius of 100 yards.

EASTERN STATES.

Boston Mortality.—According to the annual summary of deaths in Boston furnished by the Health Department, the rate for last year was 17.69 per thousand, which is a decrease of more than one death per thousand from the year before. Leaving out the infant mortality, which amounts to 28.96% of the total, the principal cause of death is no longer pulmonary and laryngeal tuberculosis, but pneumonia. The decrease in the number of deaths due to tuberculosis is no doubt due to the sanitary precautions which Boston has observed in the last few years, by the prohibition of expectoration in street cars or public places.

Adulterated Food.—From New Haven, Conn., comes the information that the Connecticut Agricultural Experiment Station has issued its eighth annual report on human food products. Over 1,000 samples were examined, special attention being paid to plain and sweet chocolate, coffee, and lard. Of 40 samples of chocolate examined, 11 were adulterated within the meaning of the law. The adulterants were usually in the form of starchy matters, used as make-weights and diluents. Each of the 17 samples of whole coffee examined was found to be pure, while out of 29 samples of ground coffee 9 were adulterated, chicory, brown lumps of wheat flour, and pea hulls being used. Lard was very largely adulterated on account of the present high price. In general, says the report, it would appear that the adulteration of food products is very common at present, but, as a rule, the adulterants used are not injurious to health.

NEW YORK.

Mortality in New York City.—Not only in New York city, but throughout the State, there was a fearful mortality during February. The bulletin of the State Department of Health shows that there were 12,749 deaths in this State during that month, an average of about 440 deaths per day. This record exceeds by almost 2,000 the average for the month during the past five years. Pneumonia was the chief cause of the increase, there being 1,820 deaths from that cause, or 14.3% of the total number.

The Queens-Nassau Medical Society held a special meeting at Jamaica, N. Y., Tuesday, March 29, and the following resolution was adopted:

Resolved, That the Queens-Nassau Medical Society hereby ratifies, approves and adopts the Agreement for the Consolidation of the Medical Society of the State of New York and the New York State Medical Association which was unanimously approved and adopted at the annual meeting of the Medical Society of the State of New York, held at Albany on January 26, 1904; and the Queens-Nassau Medical Society hereby waives notice of an application to Court for an order consolidating said corporations pursuant to the terms of said Agreement, and hereby consents to the entry of such an order without notice.

New York Hospital Still Crowded.—The current issue of *Charities* says that "a census of all the municipal hospitals and the general private hospitals of New York shows that the unusual number of patients has been continued steadily through the winter, and that the total number of patients in 20

hospitals on March 19 was greater than on January 23. On the former date the total was 5,202, and on the latter 5,390. As the capacity of the hospitals is given as 5,446, there are now, on paper, only 56 vacant beds in all the general hospitals of New York. It appears, therefore, that conditions now are really worse than in January, when there was the most talk and newspaper comment on the congested condition. But the hospitals have met the tax on their resources and, except in the municipal hospitals on the East River islands, are in good shape to deal with the epidemic of grip and pneumonia."

Bill Abolishing Coroners in New York.—An exchange says there is one good thing that the Legislature has done, and that is to abolish the antiquated and ridiculous coroner system in New York City. The bill abolishing the office of coroner passed both houses recently. Instead of coroners, who are continually at war among themselves and with the district attorney's office, there will be, at the end of the term of the present coroners, a board of medical examiners, appointed by the mayor. They will assume all the duties of the coroners, with the exception that they are to make their reports in all suspicious deaths to the city magistrates, and if an examiner is not satisfied with the result of an examination into the cause of death of a person, he is to notify the district attorney, and is then to make an autopsy in the presence of that officer and a policeman. For several years, the city authorities, aided by the medical societies, have endeavored to effect this reform, and it is cheerfully placed upon the credit side of the legislative account.

Typhoid in Watertown.—From January 1 to March 22 there were 569 cases of typhoid fever in Watertown, having a population of 22,000; the number of deaths reported to that time were 43. Dr. Geo. A. Soper, of the State Board of Health of New York, was sent to investigate the condition and reported the epidemic was caused by the polluted water used by the town. This water-supply came from Black River which has situated upon its banks above Watertown, some 30 villages and towns largely engaged in manufacturing and whose sewers, almost without exception, emptied into Black River. Dr. Soper at once instituted reforms in the town, procured water from uncontaminated source, required the registering and reporting of all cases of typhoid fever, and as a result, the epidemic is now abating. A filter plant is being constructed that it is hoped will supply pure water to the town, but opinion is expressed by those in authority that some cases of typhoid are yet to be expected for a considerable length of time. A New York exchange, commenting editorially on the subject and commending the work accomplished after the people were once aroused, says: All of this is very creditable. But how much wiser it would have been to have done these things before the calamity of a typhoid epidemic made them necessary.

Would Return the Mentally Deficient and Insane.—News from Albany states that a State board of expert sanity inspectors, to be stationed at Ellis Island, and to inspect immigrants with a view of detecting those in such stages of mental weakness as would lead to their becoming a public charge, is provided for in a bill to be introduced in behalf of the State Commission in Lunacy. Although immigration is wholly a national government affair, it is said that the United States Commissioner of Immigration is in favor of the proposition for a State board, and that the necessary permission would be granted by the general government. The United States Marine-Hospital has charge of this matter at present, but it does not employ experts in mental disease, and there is no means of detecting mental disease except through a physical manifestation of it. It is said by the chief officer of the New York City Pavilion for the Insane, that often insane patients are received who have been in the country only a few days or months. Commissioner of Immigration Williams says that whenever this proposed board should determine that an immigrant was insane at the time of his taking passage, he could be deported at the expense of the steamship company; and that if no such proof existed he could be deported at any time within 2 years at the expense of the government.

PHILADELPHIA, PENNSYLVANIA, ETC.

Summer Course in Medicine.—The Medical Department of the University of Pennsylvania will conduct, as usual, a summer school in medicine. It is announced that the course will begin on May 9 and extend over a period of six weeks. In most instances the individual courses will be limited to 10 students.

The Associated Health Authorities and Sanitarians of Pennsylvania will convene at Gettysburg, Franklin county, May 26 and 27, 1904. This will constitute the Thirteenth Annual Sanitary Convention. The subjects of smallpox and typhoid fever and of proper legislation for the prevention of the spread of these diseases will be very fully discussed. The registration of vital statistics and its importance to the well-being of the State will be presented in an address by Dr. Cressy L. Wilbur, the expert statistician of the United States Census Bureau, who for many years has been at the head of the Department of Registration of Vital Statistics of the State of Michigan.

Daily Medical Inspection of Schools.—The corps of 50 medical inspectors appointed for the purpose of making a daily inspection of the public schools, among other work, have received their final instructions from the health authorities and are performing their "new duties." The object of the inspection is to prevent the spread of contagious diseases through the schools, and to detect weaknesses that parents or teachers have overlooked.

Efficacy of Enforced Vaccination.—An exchange states that Dr. Lee, secretary of the State Board of Health, gives convincing testimony of the necessity of a compulsory vaccination law which shall apply to all portions of the State. He shows that in the smaller towns and cities where Boards of Health have power to enforce scientific precautions against the spread of smallpox the authorities have been able to check the disease. It is only in cities of the first and second class, where the authorities are handicapped and where a few persons can jeopard the safety of the entire community by resisting vaccination, that the scourge is still epidemic.

Typhoid Fever in Philadelphia.—During the week ended April 9 there were reported to the health authorities in Philadelphia 389 new cases of typhoid fever. This is the greatest number that has ever been reported in any week since the health records of the city have been kept; the number during the previous week being 321. Only three out of the 42 wards failed to report cases, these being the Ninth, Seventeenth and Thirty-fifth. In the Twenty-first and Twenty-second wards, which are supplied with filtered water from Roxborough, there were but six cases of the disease reported, which fact is considered proof of the efficiency of filtration.

Free Hospital for Poor Consumptives.—In an address lately made, Dr. Lawrence Flick stated that the Free Hospital for Poor Consumptives was seriously handicapped during the year 1903, by reason of a decrease of \$11,000 in the public contributions. He expressed the opinion that it could be attributed to the erroneous impression that Henry Phipps, who established the Phipps Institute for Consumptives in Philadelphia, had also founded the Free Hospital for Consumptives at White Haven. Concerning the work for the coming year, Dr. Flick is quoted as saying: There are 2 projects which ought to be established during the coming year. One is a convalescing farm, where the patients who recover in the sanitarium may live and work 8 hours a day, receiving \$5 and \$10 a month for their labor. He said such a farm could be made self-supporting and would pay the interest on the capital invested. He also advocated the establishment of an intermediary place between the city and White Haven for hopeless cases.

Increase in Negro Population in New Jersey.—The report of the Chief of the Bureau of Statistics of New Jersey contains information in regard to the negro population, which increased 46.6%, against an increase of 29.8% of whites from 1890 to 1900. The previous decade, the increase of white population was 27.8%, while there was a colored increase during this 10 years of 22.6%. The largest increase of negro population was in Atlantic county, where it was 674% in the 2 decades from 1880 to 1900. In Essex it was 168.2%; in Hudson, 173.2%; in Monmouth, 99.5%; in Morris, 100%; in Ocean, 175.5%; and in Union, 98.7%. The biggest increase was in the cities and seaside resort counties, where the negroes find employment as servants, while the lowest percentage was in the agricultural counties. In Warren it was 3.1%; Salem, 9.8%; while Hunterdon shows a decrease of 6.1%; Somerset, 6%; and Sussex 8.6%. The total number of negroes in New Jersey in 1880 was 38,853, and in 1900 it was 68,844, an average increase of 76.9%. The negroes make a favorable showing in general and mechanical knowledge, though they take a longer time than the whites to acquire skill. Out of 398 manufacturing establishments, representing 80 different industries, only 83 employed negro labor in any capacity, there being 963 of them, against 38,364 whites.

SOUTHERN STATES.

The West Virginia State Medical Association will hold its thirty-seventh annual meeting at Fairmount, W. Va., May 10, 11, and 12, 1904.

Has the Germ Causing Parotitis Been Discovered?—According to newspaper reports, Dr. Samuel Darling, of the College of Physicians, and pathologist at the City Hospital, in Baltimore, has isolated the germ which causes mumps.

Typhoid Fever and the Agricultural Department.—It is reported that experts in the Agricultural Department at Washington have announced the discovery of a substance which will kill not only typhoid, but many other germs in stagnant water. The substance is none other than the Bordeaux mixture, a preparation of copper sulfate, lime, and water. It is claimed that in contaminated water an amount of this mixture added not sufficient to render the water unfit for drinking purposes, will kill typhoid germs within a short time, as it does also malarial germs, the algae, and various other noxious substances. Expert sanitarians doubt the efficiency of this mixture to accomplish what is claimed by the department.

Texas Epileptic Colony.—An exchange states that the magnificent institution provided by Texas for the care of her epileptics has been formally opened. It is located at Abilene, Texas, and though not yet completed, has sufficient accommodations for 250 patients. It is built on the cottage plan, so many patients to each cottage, each of which is a complete household, with its kitchen, dining-room, servants, nurses, and its own garden for vegetables, etc. Dr. John Preston, formerly superintendent of the State Lunatic Asylum, at Austin, is the superintendent. The magnificent sum of \$250,000 was appropriated by the Legislature for this great humanitarian work. This is ahead of any State in America, excepting, perhaps, New York. The law stipulates that epileptics now cared for in the 3 insane asylums (Austin, San Antonio, and Terrell) shall be received first, and then those still uncared for, at home or in jails as the case may be, are to be admitted in order of application filed, until the full capacity is reached.

WESTERN STATES.

New Hospital to be Erected in Tacoma.—The Northern Pacific Railroad Company is soon to erect a new hospital in Tacoma, Washington, at a cost of \$100,000. The structure is to be of brick, and the employees of the railroad company are to pay 50 cents each per month from their wages toward a fund, out of which they are to be taken care of when ill or injured.

Contaminated Milk Started Typhoid Epidemic.—News from Muscatine, Ia., under date of April 4, says: Contaminated milk sold by a man whose wife was lying ill with typhoid fever is alleged to have caused an epidemic of typhoid on East Hill, a suburb of this city. Two are dead and 35 are under treatment for typhoid in this section, and it is alleged that all are users of the milk sold by this man.

Mortality in Chicago.—The Bulletin of Chicago's Health Department for the week ended April 2 says: Compared with the other large cities of the country, Chicago has come out remarkably well through the trying ordeal of a memorable winter. The 7,675 deaths reported during the first 3 months of the year represent an annual deathrate of 15.77 per 1,000 of population. For the corresponding quarter of 1903 the total deaths were 7,856, and the annual deathrate was 17.10 per 1,000, or nearly 8% (7.7%) higher.

Druggist Physicians.—A decision was handed down in the St. Louis Court of Appeals March 30, which will prevent physicians who are also druggists, from filling their own prescriptions when the principal ingredient of the prescription is whisky. The case was that of T. S. Manning, of Audrain county, who was found guilty of violating the drug dramshop law, and was fined \$100. He appealed on the ground that he was a physician and also a druggist, and had a right to prescribe whisky as a physician, and fill the prescription as a pharmacist. The court holds that the requirement of a prescription is intended as a check on the pharmacist, and that if the same man is permitted to write and fill a prescription calling for whisky the check is virtually removed, and therefore the judgment of the lower court is sustained.

FOREIGN NEWS AND NOTES

GENERAL.

Bubonic Plague in India.—From Bombay, under date of March 29, came the news that the latest available bubonic plague returns for the whole of India for the week ended March 19 show the appalling mortality of 40,527, an increase of 7,000 over those of the preceding week. In the Punjab and the Northwest provinces each there is a deathrate of 10,000 weekly; in the Bombay presidency the deaths number 8,500, and in Bengal 5,000.

Deathrate on the Isthmus.—Official reports from both sides of the Isthmus show that there were many cases of death from several causes during the week ending March 13. In Panama, where there is a population of about 18,000, there were 31 deaths during the week. This is equivalent to an annual deathrate of about 90 per 1,000 of population. The least healthful of the cities of the United States has a deathrate of only about 21. During the same week in the city of Colon, where there is a population of 8,000, there were 8 cases of death. This figures out an annual deathrate of 52. No one died, so far as was reported, of yellow fever, but there was a high mortality from other fevers and from tuberculosis. This is the dry season on the Isthmus, but there have recently been two or three heavy rains.

Miscellaneous.—Hamburg: Two physicians of the Hamburg Institute for Tropical Diseases, Messrs. Otto and Neumann, have gone to South America for the purpose of studying yellow fever. They are supplied with considerable means, furnished by shippers and merchants of Hamburg. In addition to scientific studies, they are to collect information with reference to the new preventive measure now used in South America against yellow fever, and to devise means to prevent the heavy damages which the German merchant marine has suffered

in the several years of yellow fever epidemics. Dr. J. H. van't Hoff, the eminent chemist, has been made an honorary doctor of medicine by the University of Utrecht.—**France:** Dr. Renault, a young chemist of Marseilles, has invented a tablet which not only contains enough nourishment, he claims, for a man for 24 hours, but they also act as a stimulant, and he is in St. Petersburg to offer his services to the Czar.—**Santiago de Chile:** Bubonic plague has reappeared at Antofagasta, a seaport and the capital of the Province of Antofagasta.—**England:** Dr. George H. F. Nuttall, editor of the *Journal of Hygiene*, London, and who is an American, has been nominated by the council for membership in the Royal Society, which holds its election in May. The honor is one much coveted in England and America.

OBITUARIES.

Louis A. Kengla, editor of the *Occidental Medical Times*. Dr. Kengla had suffered with an affection of the heart for some time and had been for several weeks confined to his bed. His death on March 26, while not wholly unexpected, came as a shock to the profession of the Pacific Coast, who held him in the highest esteem. Dr. Kengla was president of the San Francisco County Medical Society last year and had been secretary of the California Academy of Medicine for several years. He was a native of Washington, D. C., and a graduate of the Medical Department of the University of Georgetown, D. C., '86. The profession and the nation owe Dr. Kengla much for his fearless and noble work with regard to the plague question on the Pacific Coast.

James Brownlee Sanford, at St. Luke's Hospital, Denver, Col., from appendicitis, March 16, aged 35. He was Speaker of the House of Representatives at the time of his death and was widely known throughout Colorado and the West. He was born in Penn Yan, N. Y., was a graduate of the medical department of Baltimore University; a delegate from the state of Colorado, the National Medical Legislative League and secretary of that body; and a member of the Royal Geographical Society of London, England.

Peleg Wadsworth, at his home in Malden, Mass., April 4, from heart disease, aged 70; a graduate of Dartmouth Medical College, in 1880. During the war he served in the hospital corps of the Army of the Potomac and in the hospitals at Washington. He returned and located in Portland, Me., and subsequently in Malden, where he practised for 35 years. He was prominent in Masonic and other fraternal organizations.

J. Carroll Monmonier, at his home in Franklin, Md., April 6, aged 61. He was graduated from the Medical Department of the University of Maryland, in 1866; was attending physician at Mount DeSales Academy and Epiphany College, Walbrook. He was one time member of the Maryland Legislature and one of the best known physicians in Baltimore county.

Israel Parsons, at his home in Marcellus, N. Y., March 24, aged 82; a graduate of the College of Physicians and Surgeons, New York, in 1848. He was one of the best known physicians in the vicinity of Marcellus, and in 1899 the Onondaga County Medical Society gave a banquet in honor of Dr. Parsons' semicentenary in medicine.

Charles C. Carter, at his home in Rock Island, Ill., from pneumonia, aged 51; a graduate of Bellevue Hospital Medical College in 1876; a member of the American Medical Association, Association of Military Surgeons of the United States, Illinois Military Association and one of the best known physicians of Rock Island.

Elisha Crowell, at his home in Philadelphia, Pa., April 6, aged 76; a graduate of the University of Pennsylvania in 1851. Also a graduate in the arts of Princeton in 1849. He attained prominence during the Civil war as visiting surgeon to the different hospitals for the convalescing soldiers in the city.

John G. Brooks, at his home in Belfast, Me., March 23, aged 83; a graduate of Jefferson Medical College, Philadelphia, in 1851; at one time Mayor of Belfast. He served in the Maine State Senate in 1873 and in the lower house in 1880.

George H. Butler, at his home in New York City, March 28, aged 61; a graduate of Bellevue Medical College, New York, in 1869; member of the New York County Medical Society and the New York Academy of Medicine.

Denis N. Conner, at his home in Philadelphia, Pa., January 20, aged 59; a graduate of the University of Pennsylvania, in 1867. He was a member of the Philadelphia County and the Pennsylvania State Medical Societies.

Harry S. Dissler, of Schoeneck, Pa., from acute nephritis, at the Medico-Chirurgical Hospital, Philadelphia, at which he was resident physician, March 20, aged 22; a graduate of the Medico-Chirurgical College, in 1903.

William H. Heller, at his home in Abington, Ill., April 5, aged 82. He began the practice of medicine in Cuba in 1846 and later moved to Abington, where he had practised over 50 years.

Percy L. Jermaine, of Holton, Kan., at Stormont Hospital, Topeka, from general peritonitis, March 22, aged 36; a graduate of the Jefferson Medical College, Philadelphia, in 1892.

Harry J. Chapman, of San Antonio, Texas, was shot and instantly killed while driving, March 25, aged 37; a graduate of the University of Pennsylvania, Philadelphia, in 1895.

Horace W. Burg, of Northumberland, Pa., at the Medico-Chirurgical Hospital, Philadelphia, February 16, aged 58; a graduate of the Jefferson Medical College, in 1877.

Philander S. Brewster, of paralysis, at his home in Berwick, Pa., March 5, aged 78; he attended lectures in Philadelphia and registered under "years of practice."

Arthur R. Simmons, at his home in Utica, N. Y., March 27, from heart disease; a graduate of the College of Physicians and Surgeons, New York, in 1875.

John Paul Dombrowski, at his home in Peoria, Ill., from pneumonia, March 28, aged 47; a graduate of the University of Berlin, Germany, in 1880.

Crawford E. Fritts, at his home in Hudson, N. Y., April 6, from neuralgia of the heart, aged 54. He was one of the leading physicians in Hudson.

John Kennier Patterson, suddenly, at his home in Philadelphia, Pa., January 14, aged 61; a graduate of the Jefferson Medical College, in 1868.

Albert Stanley Dolan, at Riverside, Cal., March 21; a graduate of the University of Michigan Homeopathic Medical College, in 1882.

William E. Schlemm, at his home in Reading, Pa., February 29, aged 79; a graduate of the University of Pennsylvania, in 1854.

Guy Michener, formerly of Coles and Edgar counties, Ill., committed suicide at Guthrie, Okla., on March 29.

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended April 9, 1904:

SMALLPOX—UNITED STATES.			Cases	Deaths
Florida:	Jacksonville.....	Mar. 26-Apr. 2....	1	
Illinois:	Chicago.....	Mar. 26-Apr. 2....	5	
	Danville.....	Mar. 26-Apr. 2....	6	
Indiana:	South Bend.....	Mar. 26-Apr. 2....	1

Changes in the Medical Corps of the U. S. Army for the week ended April 9, 1904:

- ALLEN, IRA A., OLMON P. GOFF and JAMES M. FEENEY, contract surgeons, are relieved from further duty with the Eleventh Infantry, in camp, Presidio, in order to enable them to avail themselves of leaves granted in the Philippines division.
- DENNIS, MILLS, contract surgeon, in camp, Presidio, will report to the commanding officer, Eleventh Infantry, in camp, Presidio for duty to accompany that regiment to Fort D. A. Russell. Upon the completion of this duty he will proceed to his home, Temple, Tex., for annulment of contract.
- NORVELL, BONAPARTE P., contract surgeon, is relieved from further duty with the Eleventh Infantry, in camp, Presidio, and assigned to duty with the Battalion of Philippine Scouts, in camp, infantry cantonment, Presidio.
- AMES, ROGER P., contract surgeon, is granted leave for one month.
- MACY, FREDERICK S., contract surgeon, is granted leave for fourteen days from about April 15.
- NORVELL, BONAPARTE P., contract surgeon, is relieved from further duty with the Battalion of Philippine Scouts, infantry cantonment, Presidio, and will proceed to his home, St. Louis, Mo., for annulment of contract.
- MANY, HARRY C., contract surgeon, is granted leave for two months from about June 1.
- MAREE, First Lieutenant JAMES I., assistant surgeon, is granted leave for one month.
- MILLER, First Lieutenant REUBEN B., assistant surgeon, is granted leave for two months, to take effect upon his relief from duty at the Army Medical School, with permission to apply for an extension of one month.

Changes in the Medical Corps of the U. S. Navy for the week ended April 9, 1904:

- TAYLOR, E. C., assistant surgeon, detached from the Naval Museum of Hygiene and Medical School, Washington, D. C., and ordered to the Naval Hospital, Naval Station, San Juan, P. R., sailing from New York, N. Y., about April 9-April 1.
- CAMPBELL, F. E., assistant surgeon, detached from the Naval Museum of Hygiene and Medical School, Washington, D. C., and ordered to the Constellation—April 1.
- MANCHESTER, J. D., assistant surgeon, ordered to the Columbia, April 11—April 1.
- PEASE, T. N., assistant surgeon, ordered to the Hartford, April 14—April 1.
- REEVES, I. S. K., assistant surgeon, ordered to the Minneapolis, April 14—April 1.
- WENTWORTH, A. R., surgeon, granted leave for one month from April 5—April 3.
- BISHOP, L. W., assistant surgeon, detached from treatment at the Naval Hospital, Mare Island, Cal., ordered home and granted sick leave for two months—April 3.

Changes in the Public Health and Marine-Hospital Service for the week ended April 7, 1904:

- VON EZDORF, R. H., passed assistant surgeon, detailed as recorder of board of examination which met at Washington, D. C., April 4, 1904, for the examination of candidates for appointment as assistant surgeon—April 6, 1904.
- FOSTER, M. H., passed assistant surgeon, bureau letter of March 19, granting leave of absence for ten days from March 30, amended so that said leave shall be effective from April 29—April 6, 1904.
- ANDERSON, J. F., passed assistant surgeon, relieved from duty as recorder of board of examiners which met at Washington, D. C., April 4, 1904, for the examination of candidates for appointment as assistant surgeon—April 6, 1904.
- MCCLEINTIC, T. B., assistant surgeon, relieved from duty in the Hygienic Laboratory, Washington, D. C., and directed to proceed to Tampico, Mexico, for duty in the office of the United States Consul—April 2, 1904.
- GLOVER, M. W., assistant surgeon, to proceed to Vancouver, B. C., for special temporary duty—April 2, 1904.
- WARREN, B. S., assistant surgeon, granted leave of absence for six days from April 10—April 5, 1904.
- MONCURE, J. A., acting assistant surgeon, department letter granting leave of absence for thirty days from April 1, 1904, amended so that said leave shall be effective from April 10—March 31, 1904.

Board Convened.

Board convened to meet at Stapleton, N. Y., April 4, 1904, for the physical examination of officers of the Revenue Cutter Service.—Detail for the Board: Passed Assistant Surgeon A. C. Smith, chairman; Assistant Surgeon T. W. Salmon, recorder.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

AN EFFICIENT ARMY MEDICAL SERVICE.

BY

JAMES S. KENNEDY,

of Fort McDowell, Angel Island, Cal.

Late Captain Assistant Surgeon U. S. Volunteers; Contract Surgeon U. S. Army.

To the Editor of American Medicine:—It seems strange that so little, or no notice, has been taken, editorially, of the new "bill to increase the efficiency of the Medical Department of the U. S. Army," now being earnestly pressed by the Surgeon-General, and which is of the most important interest to the medical profession at large, from whence the new material must come.

This bill is simply an act of justice, as well as the entering wedge to shelve forever the impossible "contract surgeon" system as it now exists, and to increase the medical corps by a trained set of surgeons, who have already served from the first call for help, and to place it in the first class as to efficiency and service.

The main feature, as restricted to a short article, consists of a positive rank as first lieutenant, longevity of service, the privilege of quarters, allowances, etc., of the officer of the same rank in the regular corps. These features are good, but they do not go far enough. To these should be added "retirement" for long and faithful service, which is but placing it on a par with the other staff departments.

In brief this bill for the "medical reserve corps" allows for past service as a volunteer medical officer, or for service in the "reserves," and in case the medical reserve officer desires to take the examination for the regular corps, and provided he has three or more years of service, he is, if passed, made a captain at once and not as a former correspondent stated, have to wait for from five to eight years for a captaincy.

Better than all else, this bill will do away with the impossible contract system entirely, and in its place there will be organized a commissioned force of experienced medical officers (reserve) with actual rank and its privileges, and in number no more than are now serving under the present regime, for the Surgeon-General will not recommend any officer for appointment who has not passed a satisfactory examination, and whose services have not been of the highest character as to efficiency and professional ability.

There are several changes that would make this bill as near perfect as possible, one of which is the question of relative rank. The new bill states that the officer entering the "reserves" must take rank next after all other lieutenants of the line or staff. Far better would be the plan that worked so smoothly in the volunteer medical corps during the campaign in Cuba and the Philippines—that of taking rank according to date of commission—but in the bill as it is now those who have served since the first call would have to come in after the recent graduate, who has had no service at all.

As a class we are much pleased to see the interest taken in this bill by the different societies at large and resolutions are looked for from the National Associations, urging their representatives to take this matter up with the Committee on Legislation, and the added influence of personal adherents on the floor of the House and Senate.

We also owe much to the brilliant ex-Governor of the Philippines—now the Honorable—the Secretary of War—who has been in constant contact with the medical officers, constituting the Contract Surgeons of the U. S. Army in the Philippines, and who has favorably endorsed this bill on account of his personal knowledge of the difficulties under which the contract system worked.

To the present Surgeon-General of the U. S. Army, for his earnest efforts in the passage of this bill, and for his sense of respect and courtesy due to the contract surgeons as professional men, and universal kindness to us as a class, Surgeon-General O'Reilly has earned the undying gratitude, the sincere

respect, admiration, and esteem of every member of the medical corps who has gone into the army as a contract surgeon, or who has served under him in the volunteer medical corps.

Speaking as a member of the late volunteer medical corps and as a contract surgeon, who has the best interest of this bill at heart, and who, from personal observation, having served in both capacities, is familiar with the sacrifices made and the injustice of the present system, earnestly solicit the power and influence of your pen in securing the favorable consideration of this bill by the Senate and the House, and also to further the adoption of the "retirement" clause as well as the actual rank from the date of commission.

By so doing you would be conferring an incalculable benefit and favor to the medical men who are now serving as contract surgeons in the United States Army.

A CASE OF RABIES AND ONE OF UNDIAGNOSED FEVER.¹

BY

CARL S. TOMPKINS, M.D.,
of Randolph, N. Y.

HYDROPHOBIA.

CASE I.—The patient was G. K., a school boy, aged 11. Family and personal history are good. About January 22 he was bitten on the left hand by a strange dog. The wound was not cauterized, but the hand was soaked in warm salt water. His health was good until the evening of March 2, when he complained of feeling tired. He lay on a couch all the evening, which was very unusual for him. He did not go to school March 3, on account of headache and feeling tired out. He did not sleep well that night, vomited frequently, and choked when he tried to drink.

On March 4 the patient behaved peculiarly all the morning. About 2 p.m. he began screaming and running about the room. He had a sensation of smothering, and would turn his head away from water when it was offered him.

At 3 p.m. Dr. Arthur Sage was called, and found the patient in a state of marked mental excitement. Temperature at that time was 100.5°. Bowels and kidneys had been acting normally.

He slept about two hours that evening. At 11 p.m. he became violent. The doctor was called, and he gave the patient a tablet, which he swallowed. He was offered water; he took one swallow, and jumped to the center of the room. He had no fear of water before trying to swallow it, but after that refused to take it into his mouth.

He talked ramblingly, but coherently. He was rational at intervals. He had hallucinations of seeing cats and dogs, made a peculiar cry that might be thought to sound like the barking of a dog, and tried to bite the doctor.

He began frothing at the mouth at midnight; this condition continued throughout the night, except when controlled by morphin.

On March 5, at 8 a.m., temperature was 103° by axilla, pulse 120. There was tremor and twitching of the eyelids.

During the morning spasms of the legs appeared, rapid kicking of the legs rather than spasms of groups of muscles. This was controlled by morphin, and he was given a large dose before being taken on the ambulance; he was in a comatose state when he entered the hospital at 4 p.m.

The stupor diminished in the course of half an hour, so that he recognized his father and mother. The spasms of the legs returned, but there was no twitching of the eyelids. He was given no more morphin. A small dose of bromid and chloral was administered per rectum. He would take nothing by mouth.

Temperature per rectum was 106°, pulse 130, when he entered hospital. By 7 p.m. convulsions had stopped, and he passed into a stupor, from which he did not rally.

Death occurred at 9 p.m.

Autopsy.—The coverings of the brain and cord appeared somewhat red. No other pathology found.

Portions of the spinal cord were removed by Dr. Matzinger. Two rabbits were trephined and subdural inoculation of a solution of the cord made. Both rabbits developed the paralytic form of rabies, one dying on the seventeenth, and the other on the nineteenth day.

AN UNDIAGNOSED CASE OF FEVER.

CASE II.—L. A., aged 22, born in southern Italy, is a laborer, and single.

He entered Buffalo General Hospital February 18, 1903, and was discharged April 1, 1903.

Family History.—Good.

Personal History.—The patient came from Italy 11 months

before entering hospital. He had been sick only once before—that was two years ago. He was in bed one month, had fever, and lost weight. He thinks his fever was high for two or three days at a time, then two or three days would intervene without fever. He had no chills, epistaxis, nor diarrhea. He never had a chill before or since.

Present Illness.—One month before entering the hospital he had to stop work and go to bed. He had fever, headache, loss of appetite, and had lost weight.

A few days before entrance he expectorated a little blood. He feels about the same as he did when sick two years ago, but worse.

Physical Examination on Entrance.—Lungs clear; first heart sound weak; second pulmonic somewhat accentuated; spleen palpable, large and firm.

Temperature was 98°, pulse 120, respirations 20 when entering February 18.

Temperature remained at 98° until 2 a.m., February 20, when it was 97°, but it returned to 98° at 6 a.m. Pulse had dropped to 60. Respirations did not rise above 25 throughout illness. Temperature rose gradually until at 2 p.m. on February 21 it reached 103.4°; at 6 a.m., February 23, it was 99°; at 6 p.m., 106.2°; at 10 a.m. February 24 it was 98°; at 6 p.m., 104°; at 6 a.m., February 25, it was 97°; at 6 p.m., 103.4°; at 2 a.m., February 26, again 97°.

Pulse followed rises in temperature, 120 being the highest. No antipyretics were used. When temperature was 102.5° or above, a cold sponge or a hot mustard foot-bath was given.

Two more periods of high temperature occurred, but were not so severe. At 2 p.m. on February 28 the temperature had risen to 103.2°, and at 6 p.m. on March 4 it was 103°.

On March 4 quinin was administered in 60 cg. doses at 10 a.m. and 12 m., and continued until March 18.

The temperature did not rise above 99° after March 4, except that on the evening of March 8 it reached 101°. Bowels had not moved for 36 hours. Temperature dropped to normal in four hours after a bowel wash was given.

The meager history was obtained through an interpreter. It was impossible to determine whether he had been given an antipyretic before entering the hospital.

At no time did he have a chill. He was not extremely prostrated, and was never delirious.

Special Examination.—Urine practically normal; first examination showed a faint trace of albumin.

Sputum.—February 25, streptococci, staphylococci, and a few pus cells present.

No tubercle bacilli, diplococci of pneumonia, or bacilli of influenza found.

Blood.—February 20, hemoglobin, 65%; erythrocytes, 4,400,000; leukocytes, 7,600. Differential count of leukocytes:

Lymphocytes (small), 25%.

Lymphocytes (transitional and large), 6%.

Polymorphonuclear neutrophils, 65%.

Eosinophiles, 3%.

Plasmodium of malaria was not seen. Frequent examinations for the plasmodium were made, but it was never found.

Widal reaction was positive on February 27. Stools were not of a typhoid character.

ANAESTHOL.

To the Editor of American Medicine:—We herewith state that the use of the name of Dr. Willy Meyer, of New York, upon the label of the new anesthetic "Anaesthol" was made without his knowledge, though in entire good faith upon our part.

At his request the label has been changed and, in order to protect the medical profession against unreliable imitations, it will henceforth bear the name of Dr. Weidig, the originator of the new compound.

LEHN & FINK,

Sole Manufacturers.

Women Physicians.—The question of the suitability of women for the medical profession has been raised again by the action of the Western Infirmary, Westminster, in dispensing with the services of a lady doctor after a probationary of 3 months. There was no question of incapacity raised in this instance; but the decision to cancel her appointment was purely the result of what is called prejudice. With this prejudice we must confess to have considerable sympathy. That it is a good thing for some women to enter the medical profession we have no doubt; but it must remain a profession for women of exceptional nerve and capacity. It must not count as one among many professions of equal suitability for all women of the intellectual ability to enter it, for a nervous breakdown, as we were tragically reminded not long ago, is far more serious in the case of a woman than a man. It is a question not of the equality of, but of the difference between the sexes.—[Lancet.]

¹The cases occurred in the Buffalo General Hospital, service of Dr. Charles Stockton.

A REVIEW OF LITERATURE RELATING TO SERUM DIAGNOSIS.*

BY

RANDLE C. ROSENBERGER, M.D.,
of Philadelphia.Associate in Bacteriology, Jefferson Medical College; Director of the
Clinical Laboratory of the Philadelphia General Hospital.

(From the laboratories of the Jefferson Medical College Hospital.)

It is not my purpose to attempt an exhaustive review of all the literature bearing upon this interesting subject, but to include, so far as possible, the most recent progress in serum diagnosis.

As is well known, the first application of serum reaction to diagnosis was in enteric fever. Ross claims that the discovery should be accredited to Grünbaum who, in 1896, while working in Gruber's laboratory, in Vienna, obtained positive agglutinative reactions in typhoid fever. The first test was made on March 14. This discovery was promptly corroborated and quickly followed by other investigators obtaining agglutinative reactions in other diseases and with other bacteria. As examples of the widespread application of the test, the following organisms are now agglutinated by the serum in their selective cases: *Streptococcus pyogenes*, diplococcus of pneumonia, bacillus of plague, colon bacillus, bacillus of dysentery (Shiga), paratyphoid bacillus, paracolon bacillus, Gärtner's bacillus, Booker's bacilli, staphylococci, gonococcus, spirilli of cholera and of relapsing fever, bacillus of tuberculosis, members of the proteus group, bacillus of tetanus, *Oidium lactis*, bacillus of diphtheria, and others. Not only are bacteria subject to this reaction, but animal parasites, as the trypanosomes, have been agglutinated by the serum of patients suffering from sleeping sickness and trypanosomiasis fever.

Freyer¹ claims that the blood of all native Indians possesses agglutinating power in health, but this statement is contradicted by W. C. Brown,² who made a number of tests with negative results.

Technic.—The technic of the Widal test is perfectly simple, and usually consists in bringing together the bacilli in young bouillon culture, or a water suspension from an agar culture, and the serum of the individual in a proper dilution. The culture should not be over 24 hours old, and the bacilli actively motile, although dead typhoid bacilli may also be used for the reaction. Examine the culture before beginning the test, to see that clumps are not present. If they exist, the culture should be filtered through paper and the filtrate used for the test. The blood or serum may be collected in various ways: (1) By a capillary pipet in which coagulation and separation occur; (2) by the white blood cell pipet in which a dilution of 1 to 20 is made; (3) obtain pure serum from a blister; (4) dried blood may be used.

The technic employed at the Jefferson Hospital and Philadelphia Hospital is the use of a nonincubated bouillon culture of the typhoid bacillus not over 24 hours old, mixing 1 drop of this culture with 1 drop of diluted blood. The dilution of the blood, 1 to 20, is facilitated by means of the pipet used for counting leukocytes; using a drop of each, a dilution of 1 to 40 is obtained; 30 minutes is given as the time limit.

Haedke³ recommends the mixture of a loop of solid culture with typhoid serum on a glass slide. McWeeney,⁴ by mixing 1% serum in a hanging drop with bouillon culture, and placing in the incubator at 37° C. for 4 hours; twisted and convoluted chains of motionless bacilli will form if the case is one of enteric fever.

When a test is made with dried blood, it must be moistened with distilled water, the difficulty of obtain-

ing an accurate dilution being one objection to this method. There is much difference of opinion as to just how much the serum should be diluted. Most observers recommend a dilution of 1 to 20; or 1 to 40; some use 1 to 200, and even 1 to 20,000 has been found effective in an occasional case. It has been found very often that the reaction is negative with dilution of 1 to 20, and positive with dilution of 1 to 50, and *vice versa*. This apparently is accounted for by the presence of certain bodies—proagglutinoids, described by Shiga⁵—that develop from the agglutinins and combine with the bacilli, but lose the power of combining with the agglutinin. These bodies—proagglutinoids—are developed from the agglutinins through extraneous influences, and possess a greater affinity for the bacilli than the unchanged agglutinins, having lost their agglutinophore group, but retaining the haptophore group; they have been produced artificially by heating dysentery-immune serum to 60° C., or by shaking with chloroform, or exposing it to sunlight for a few days (Eisenberg and Bail). Coleman and Buxton⁶ insist upon a dilution of 1 to 50.

J. S. Billings, Jr., uses a dilution of 1 to 20; clumping and death of the bacilli must occur in 10 minutes.

Bryant⁷ says that in Guy's Hospital it is customary to use 50%, 5%, and 0.5% dilution and Widal's reaction is not considered positive unless clumping and immobility of the bacilli occur with the 1 to 200 dilution within half an hour. Examinations made before the eleventh day of the disease with a negative result are of little value. In this connection he mentions W. C. C. Pake's analysis of 304 consecutive cases, in which the error was only 3.03%.

Baltharde⁸ states that by the injection of nonfatal doses of the typhoid toxin an antityphoid serum possessing agglutinating power of 1 to 100,000 but without decided bactericidal action (*in vitro*) may be obtained.

Libman⁹ claims that if the blood is employed immediately after drying, the result is not so good as when it is used some hours later. However, in the summer, if the blood is not taken for the test within 24 hours, it is not so easy to obtain the Widal reaction.

Ficker¹⁰ has perfected a fluid to which he has applied the name diagnosticum, with which it is possible to obtain the Widal reaction without the necessity of living cultures of typhoid bacilli. The fluid is sterile, slightly turbid, and is said to keep well for 9 months. The reaction is perceptible to the naked eye, absolutely unmistakable, and occurs at ordinary room temperature. "The fluid is derived once from one and the same typhoid stem."

A. J. Wolff¹¹ recommends smearing an agar slant with typhoid feces and from the growth resulting, inoculating 1 or 2 tubes of bouillon. The bouillon must react from 1% to 2% alkaline with $\frac{N}{10}$ acid, using phenol-

phthalein as indicator. A sample of the blood is taken and mixed with the bouillon culture and placed under the microscope. If there is sufficient agglutinative material present, the typhoid bacilli will clump while the colon bacilli remain active. In 35 tests thus made, every case that gave a positive reaction by this method proved to be typhoid fever.

Proescher¹² recommends collecting the blood in U-shaped tubes of a diameter of 2 mm. The tubes are closed, centrifugalized, and the serum separated by breaking the tube with a file. The serum is then transferred by capillarity from the tubes to pipets graduated in 0.01 cc. This is then diluted in 1 to 10 normal salt solution, and portions are placed in small test-tubes, the first part without additional dilution, the second diluted one-half, and so on through 5 dilutions. Each tube then receives 5 cc. of typhoid bouillon culture, which, after 24 hours' growth, has been killed by adding 1% formalin. This diluted culture is then added to the tube, in quantity equal to that which the tubes already contain. The tubes are at once emptied into small glass

* Read before the Pathological Society of Philadelphia, February 11, 1904.

dishes and placed in the incubator for 1 to 2 hours. After this they are examined with relatively low powers (about 50 diameters) when the agglutinative masses can readily be seen.

The reaction occurs, by the methods just given, in from 15 minutes to 2 hours; while in the macroscopic test in which a small tube of the culture has added to it blood or serum from the patient, 5 or 6 hours is necessary for the reaction to be completed.

In the microscopic test a positive reaction is said to occur when all the organisms in the field, group or agglutinate and motility ceases. In the macroscopic or tube test a positive reaction is said to occur when the uniform turbidity clears and the bacteria settle in small masses at the bottom of the tube.

A. E. Wright,¹³ in the case of patients suffering from or preventively inoculated against tuberculosis, uses a suspension of extremely fine detritus of tubercle bacilli in carbolized water. By employing 1 to 1,000 solution of common salt to dilute the serum, instead of 8.5 per 1,000 solution prescribed by Koch, fallacious agglutinations and precipitations are completely avoided.

Wright's modification of Koch's procedure is as follows:

A minute quantity of powdered tubercle bacilli is placed in an agate mortar, to which is added, drop by drop, a 0.5% solution of carbolic acid. After triturating for a few minutes the turbid suspension is siphoned into a capsule. After sealing the ends of the capsule it is centrifugalized and the supernatant milky fluid, which separates in a few minutes, is used for the test. The blood is obtained in a special capsule, which is then placed in a centrifuge until the serum separates from the cellular elements. A capillary pipet is then used, and into this is aspirated one volume of the undiluted serum, and one volume of the test fluid described before. This mixture is expelled, and after thoroughly mixing upon an ordinary microscopic slide, exactly one volume is reaspirated into the stem of the pipet.

Having divided off with a suitable bubble of air, there is introduced into the stem of the pipet one volume each of serum and of the inert diluent (1 to 1,000 solution of sodium chloride). These two last mentioned volumes are again expelled, and after mixing, constitute the quantity of diluted serum for our second test dilution. Having mixed this on a slide the mixture is again reaspirated, and as in the former case and all subsequent dilutions, using exactly one volume of the mixed fluids. Another serum dilution is now made, employing for this purpose a full volume each of two-fold dilution of serum and of the inert diluent. We then fill upon these principles in succession (into the stem of our pipet) a series, ordinarily 7 or 8 graduated dilutions of serum mixed in each case with a precisely equivalent volume of the bacterial suspension. Completion of the series is reached by introducing into the pipet a mixture of equal volumes of the inert diluent and test fluid to serve as a control. The pipets are then sealed and placed upright in the incubator or on the laboratory bench. After an interval of 12 hours, flocculation and deposition associated with a corresponding clearing of the supernatant fluid takes place. The precipitate in the two-fold dilution is in most cases—presumably as a consequence of bacteriolysis—markedly less in bulk than the precipitate in the succeeding dilution. After standing for a long time, a deposit makes its appearance also in the higher dilutions of the serum and in the control.

Besides tuberculosis, this method is also useful in those suffering from or preventively inoculated against typhoid and Malta fevers.

Romberg¹⁴ recommends mixing a dry culture of tubercle bacilli with 1 liter of bouillon containing 5 grams of carbolic acid. For use 1 part of this is mixed with 3 parts of distilled water. One part of serum extracted by wet cups is added to 5, 10, 15, or 20 of the emulsion which is left in the tubes. If at the end of 24 hours this becomes clear, the reaction is considered positive. The test is not entirely reliable.

Koppen¹⁵ treats the tubercle bacilli with caustic potash solution, thus saponifying them. The stem fluid which he uses for the agglutination test is milky, and homogeneous, and does not become putrid. After this saponification the tubercle bacilli take the stain as readily as before.

Thellung¹⁶ finds that agglutinins can be produced by the injection of tuberculin into guineapigs and rabbits. It is also claimed that the agglutination does not occur constantly or regularly in tuberculosis.

Lagriffoul,¹⁷ in the serum diagnosis of tuberculosis, adopts the technic of Arloing and Courmont. The cultures are made in a 2% peptone medium containing 6% glycerin. This medium is reinoculated every 20 days and incubated at 30° C. with agitation once daily. Macroscopically the test was facilitated with dilutions of 1 to 5, 1 to 10, and 1 to 15.

Loeb¹⁸ uses an 8 to 12-day old culture of the tubercle bacillus previously grown on potato and homogenized. To this is added clear blood-serum or serous effusion in the proportion of 1 to 5 or more. This is followed if the reaction is positive by a flocculent precipitate in the course of 6 hours.

Neufeld¹⁹ studied the agglutinative action of the serum of immunized animals on cultures of the pneumococcus in broth by the usual methods and was thus the first to note typical agglutination reactions in various dilutions, both microscopically and macroscopically. In dilutions of 1 to 50 he was able to obtain the reaction in from 15 to 30 minutes.

Bezancon and Griffon²⁰ inoculated 1 cc. to 2 cc. of clear undiluted serum with pneumococci and observed the appearance of the growth, at the end of 15 or 16 hours' incubation, to be characterized by the formation of a membrane at the bottom of the tube. This membrane consisted of branches and chains of pneumococci; this so-called agglutination can be observed by the unaided eye. These two observers then applied the method to 186 patients, among these being 64 of undoubted pneumococcus infection. In the serum from these patients the growth in bunches and chains was observed easily and constantly. The dilutions used were 1 to 50; they found that the results were very uncertain.

Weaver²¹ in testing the agglutination reaction in scarlet fever patients and others, used cultures of the streptococcus in bouillon which was neutral to litmus and 1% acid phenolphthalein. The blood was obtained from a vein of the arm and serum allowed to separate from the clot in an icebox. The serum was diluted with the same bouillon as used for the culture in strengths of 0.5, 0.25, and 0.125; by means of pipets of uniform size, one part of these various strengths was added to 30 parts of the 24-hours' bouillon culture. The mixtures of serum and culture were then placed in small test-tubes each containing about 1 cc. kept at room temperature and examined. If a positive agglutination reaction took place, a sediment formed at the bottom of the tube made up of flakes and granules, which would not break up upon agitation. The agglutination takes place more rapidly in the incubator than at room temperature, often being complete in 1 hour and usually in 3 to 5 hours; at ordinary room temperature agglutination took place in 18 to 24 hours.

Wadsworth²² in the agglutination tests in cases of pneumococcus infection in man and animals, uses a peptone broth made from meat infusion, which has been carefully neutralized before boiling. In a flask containing 200 cc. of this medium, the maximum growth of the pneumococcus was evident in 24 or 36 hours. At this stage the culture was centrifugalized, the clear fluid decanted, and the sediment shaken with about 15 cc. of isotonic (0.85%) salt solution. This left a dense, finely divided suspension of pneumococci, less than 48 hours old. Dilutions, with the serums to be studied, were then made in small, slender tubes and observed for some 12 to 18 hours at 37° C. The more marked reactions may be complete in 5 or 6 hours or less, but 12 or more hours are often required to bring out the more delicate tests. Serums stored in the icebox were found to be active for 4 or more months; the lytic power was gone, and the agglutination did not appear in high dilution; but in low dilutions immediate and complete reactions took place.

The normal serum of the rabbit always failed to agglutinate the pneumococcus cells. This was also the case with the serum of the cat and dog. Normal

bullock's serum, however, gave some very marked agglutinations, even in dilutions of 1 to 50. Ascitic fluids tested also failed to agglutinate in dilutions of 1 to 5, and 1 to 15, but normal serums (human) gave reactions in dilution up to 1 to 10 in less than 18 hours; 1 to 30 failed to agglutinate. In 3 cases of lobar pneumonia positive reactions were obtained in dilutions of 1 to 10 after 5 hours' incubation.

Cairns²³ insists upon a perfectly homogeneous culture of *Bacillus pestis* for the serum diagnosis of the disease. For the reaction he uses a small test-tube 9 cm. in length and 0.7 cm. internal diameter, into which a drop of the blood-serum (collected in a small Pasteur pipet) is placed, and then the culture of the organism, up to the required dilution. The cultures are prepared by taking a 24 or 36-hour incubated growth upon agar, and filling with 0.75% sterilized salt solution to cover the solid medium. The growth is then as far as possible transferred to the salt solution by rubbing the surface of the agar with the blunt end of a Pasteur pipet. These emulsions are then set aside in a sterile test-tube for a short time, to allow any cohering masses to settle. A too concentrated emulsion is agglutinated very slowly and often very imperfectly; while the exact degree of dilution is undoubtedly a matter of some importance, it can only be determined after considerable experience in agglutinative work. The tubes are then set aside and when complete sedimentation occurs—18 to 24 hours—a positive reaction is recorded.

Klein,²⁴ in preparing a homogeneous culture of *Bacillus pestis* for the agglutinative reaction, used a gelatin culture distributed in a 0.75% physiologic salt solution. His reason for using a gelatin culture is that, in his opinion, the surface colonies upon this medium are less viscid and drier than those upon agar. "If to a good salt emulsion of plague bacilli—taken from the gelatin surface—bouillon is added in the proportion of 1 of bouillon to 20 of emulsion, the result of positive agglutination is evident in from 12 to 15 minutes." Experiments were then made with blood of rats that had been injected first with Haffkine's prophylactic, then with small doses and finally larger doses of living plague organisms. Klein found that in several animals thus treated, 3 and 5 weeks after recovery, agglutination took place in dilutions of 1 to 20, and 1 to 40, in 10 minutes.

McFadyean²⁵ showed that serum from horses with glanders possessed the power of agglutinating glanders bacilli. In the great majority of cases of glanders a 1 to 50 dilution of the serum produces marked agglutination in a few minutes, while in that of nonglandered animals no effect is produced under these conditions. He finds that a more delicate and reliable method is to grow the bacillus in bouillon containing a small proportion of the serum to be tested. In this way he has obtained a distinct sedimenting action with a serum, which did not agglutinate at all distinctly in the ordinary method.

Heanley,²⁶ in testing the sedimentation and agglutination reaction in cases of glanders, used one part of glanders serum diluted with 109 parts of normal salt solution, and 110 parts of emulsion of glanders bacilli in normal salt solution. The same procedure was adopted with 2 samples of serum from diphtheria patients. When examined in 10 hours the glanders specimen showed definite sedimentation, the others did not. A repetition of the experiment gave the same result, and a dilution of 1 in 505 also proved positive; typhoid and normal serum showed no sedimentation.

The glanders serum could be differentiated from the others in about 4 hours, but the reaction became more obvious later. Eleven tubes containing blood were numbered, and included blood from 1 normal person, 2 from enteric fever patients, 2 patients with scarlet fever, 2 with glanders, 1 with tuberculosis, 1 with scarlet fever and diphtheria, and 2 patients with diphtheria. Dilutions of 1 in 505 were made and only the 2 glanders

specimens gave the reaction. In another experiment samples of blood from 2 patients with enteric fever, 2 with scarlet fever, 2 with diphtheria, 2 with variola, 2 with glanders, and 2 specimens of normal blood were examined in dilutions of 1 in 220, and 4 tubes showed sedimentation. Dilutions of 1 in 505 were then made, and all showed sedimentation. These 4 cases included 2 cases of glanders, 1 of variola, and 1 of scarlet fever. With dilutions of 1 in 2,500 sedimentation was produced only in the glanders cases. In the microscopic agglutination test an emulsion of bacilli was made from a growth on sloped glycerin agar by half filling the tube with previously boiled salt solution and gently agitating for a few minutes. In one series of observations, a 36-hour culture was used and the serums and emulsion were mixed on a slide and covered by a cover-glass. Serum from a patient with glanders of 6 months' duration was diluted with 9 times its volume of normal salt solution, and then 10 of bacterial emulsion was added, making a dilution of 1 in 20. Serums from 2 patients with diphtheria were treated in the same way. It was found that in mixtures containing the serum of the diphtheria patients, clumping was marked, while in the preparation containing the glanders serum more bacilli were free than clumped. In using diphtheria antitoxin as the diluent of cultures, clumps were also quickly and completely formed.

Typhoid.—In typhoid fever the reaction sometimes is absent throughout, and this may be due to a too high dilution, therefore, a low dilution, 1 to 20, or 1 to 10 in some cases, should be used. Curschmann²⁷ claims that the reaction takes place only in the minority of cases before the termination of the first week; most frequently not until the second week, while rarely it is delayed beyond that time. Complete absence of the reaction is one of the rarest exceptions. Kennedy²⁸ claims that Widal's reaction may be present as early as the fourth day and may be continuously or intermittently present throughout the disease, or in unfavorable cases it may be absent altogether in the first few days. To obtain the full value of the reaction, tri-daily tests should be made throughout the disease.

In 165 cases of enteric fever, Libman²⁹ obtained a positive reaction with 1 to 20, and 1 to 50 dilutions in 127 cases. In some instances as many as 16 days elapsed before the reaction was positive in 1 to 50, and in 8 cases that were positive in 1 to 20, there was no reaction in a dilution of 1 to 50. He claims that it is essential in performing the test that at least two dilutions should be made—1 to 20 and 1 to 50.

Cabot,³⁰ in a collated series comprising 5,978 cases of enteric fever, has found that a positive reaction occurred in 5,814 or 97.2%, while in 5,668 control cases, a positive reaction occurred in 323 or 5%. Gwyn and Block, in 151 cases of enteric fever, obtained a positive reaction in 144. In 4 cases it developed on the twenty-second, twenty-sixth, thirty-fifth, and forty-second days respectively. In only 26 cases was the reaction present before the seventh day of the disease. Stengel and Kneass,³¹ in 2,392 collated cases of enteric fever, found that a positive reaction was obtained in 2,283, and negative in 109 cases. Coleman and Buxton³² state that Brill finds that of 4,879 cases of typhoid, the Widal reaction occurred in 4,781, or 97.9%. The reaction is absent in paracolon infection.

S. S. Adams³³ reports that of 70 cases of enteric fever in which the Widal test was made, 50 gave positive reactions. Widal³⁴ states that the agglutination reaction fails in 1 case out of every 40 of enteric fever. He has seen it as early as the third day. The most reliable results are obtained during the second week. It may be positive in dilution of 1 to 8,000.

Allaria and Bozzolo³⁵ show that *Bacillus typhosus* may be recovered from the spleen and other organs of the newborn at autopsy, when before death the Widal reaction was negative. In 4 out of 11 cases a positive

reaction was obtained at varying days following birth. In 2 cases placental blood gave a positive, and the blood of the newborn a negative reaction.

J. S. Billings,³⁶ in 1,908 specimens of blood examined during 1901 by the Board of Health, found that 304 showed a positive reaction, and 111 cases were considered typhoid clinically, although the blood was doubtful or negative. In 131 cases in which the reaction was doubtful, and in 1,362 in which it was negative, the cases proved not to be typhoid. In a large number of the positive cases the reaction was not obtained until the seventh or eighth day. In a comparatively large number several examinations were made with negative results, and yet the autopsy showed the correctness of the clinical diagnosis. It, therefore, follows that although a positive reaction may be taken as meaning typhoid with almost absolute certainty, yet a negative result does not by any means preclude the possibility of typhoid, and demands that another specimen be sent if the clinical signs persist.

Libman,³⁷ in 3,514 tests in 816 cases, comes to the conclusion that the Widal reaction, when positive, always means the presence or preexistence of typhoid. Partial reaction should be negative, and a negative reaction does not exclude the existence of typhoid. Wilson,³⁸ in a study covering 1,650 blood-examinations for the Widal reaction, states that less than 7% are what might be called partial or incomplete. They occur with much greater frequency in tuberculosis and malaria than in typhoid. Wright and Semple³⁹ report 18 cases of enteric fever in which, after subcutaneous injections of 1 cc. of sterilized cultures of *Bacillus typhosus*, the blood of the patients caused arrest of motility and agglutination of bacilli as seen in Widal's reaction.

McFarland and Anders,⁴⁰ in reporting 230 cases of enteric fever, obtained positive reactions in 219, or 95.64%. Of these 219 cases, 128 showed the reaction before the eighth day, 36 during the second week, 45 between the seventeenth and twenty-first days, 8 not until the twenty-fifth day, and 2 as late as the twenty-eighth day.

Vickery⁴¹ obtained a positive Widal reaction in 41 out of 49 cases of enteric fever. Sears,⁴² in 203 cases of typhoid fever, obtained the Widal reaction in 168, and negative results in 33. Ruediger⁴³ in 30 cases of enteric fever, obtained a positive Widal reaction in 26 cases.

Elsberg,⁴⁴ in 36 cases of enteric fever, found the reaction present in 8 cases one month after convalescence. Hektoen,⁴⁵ in 2 cases of typhoid fever that were at first confounded with scarlet fever, obtained pure cultures of the typhoid bacillus from the blood, which in each case was agglutinated by the serum of the patient. Thacher⁴⁶ cites an observer who had applied the Widal test in 334 cases. He found it present in only 6% at the end of the first week, in 36% at the end of the second week, 67% at the end of the third week, and 94% on the thirtieth day. Dun⁴⁷ reports a case of typhoid fatal on the thirteenth day. The Widal reaction was absent on the eleventh and twelfth days. He mentions that Wright (Glasgow) has observed that in severe cases the reaction is frequently absent.

Haim,⁴⁸ in a case of typhoid fever, isolated from the stools *Bacillus proteus vulgaris* which was agglutinated by the serum of the patient in dilution of 1 to 50. Widal's reaction was also positive in dilution of 1 to 50.

Harrington,⁴⁹ during an epidemic of typhoid fever, found that of 90 cases in which the Widal test was performed, 58 were positive, 25 negative, and 7 unsatisfactory for "various reasons." In some of these, 2 or 3 examinations were necessary before a positive reaction was obtained.

Pallard⁵⁰ has shown that in typhoid spine (*spondylitis typhosa* of Quincke, 1899) the Widal reaction becomes more marked and increases with the augmentation of the spinal symptoms. He concludes that the condition is an osteomyelitis due to the Eberth bacillus.

Carr and Roughton⁵¹ report a case of sapremia in which, in the first days of the disease, a positive Widal reaction was obtained, but after 6 weeks failed to give the reaction.

The writer contributes 134 cases of enteric fever, of which 109 gave positive, and 25 negative reactions. In 153 cases other than enteric fever, a positive reaction was obtained in 4 cases each of influenza and pleurisy, 1 each of malaria, peritonitis, parotitis, and pneumonia. A number of cases of typhoid fever in which a negative reaction was obtained, were diagnosed as "abortive typhoid."

Browne and Crompton⁵² state that Widal, in the examination of 40 cases of typhoid, found 11 that gave the reaction long after convalescence. One reacted 8½ years after with a dilution of 1 to 18,000. Browne and Crompton examined 68 cases from 1 to 48 months after the attack. Only 3 gave positive reactions in dilutions of 1 to 20, or 1 to 50. One of these was a case of biliary calculi, and they think that the late reaction was due to the persistence of the bacillus in the gallbladder.

Fison,⁵³ in 21 cases, found 18 that gave a positive reaction from 3 months to 8 years later. Dilutions used were 1 to 2, 1 to 9, in 30 minutes. Renard,⁵⁴ in 104 cases of enteric fever, obtained a positive reaction in 35, 5 of these being 20 years after the attack. Dilutions were 1 to 10.

Stern and S. Klower,⁵⁵ in 100 persons ill with diseases other than typhoid fever, obtained a positive Widal reaction with the typhoid bacillus in 25 cases, with a dilution of 1 to 10; in 10 with a dilution of 1 to 20; 2 in which a dilution of 1 to 30 was used, and 1 in which a positive reaction occurred in dilution of 1 to 40.

Lagriffoul⁵⁶ in cases of divers affections, including bronchiectasis, brown induration of the lung, syphilis, osteosarcoma of the knee, neurasthenia, disseminated sclerosis, pneumonia of the aged, and 1 case of typhoid fever, found the Widal reaction negative. The reaction was positive, however, in 9 cases of typhoid, 1 case each of articular rheumatism, enteritis, syphilitic fever, and hemichorea.

Zupnik⁵⁷ obtained a positive Widal reaction in 4 of 6 cases of Weil's disease, 6 of cholelithiasis, 1 of cholangitis, 1 of carcinoma of the liver, all of which were complicated by icterus. Eckardt⁵⁸ records 2 cases of Weil's disease in which the blood gave the Widal reaction with the typhoid bacillus in dilutions of 1 to 1,000 after 2 hours. Joachim,⁵⁹ in a patient suffering from purulent cholangitis and one of carcinoma of the ductus choledochus, obtained a positive agglutination reaction with *Bacillus typhosus*, the cholera spirillum and *Bacillus pyocyaneus*. In the latter case the test failed in high dilution, while it was positive in the first case in dilution of 1 to 50. Koehler,⁶⁰ in 10 cases of disease of the liver, of which 8 were icteric, found an agglutination with the typhoid bacillus present in 6. The highest dilution employed was 1 to 50, although 1 to 40 was generally used, and once 1 to 10.

Magele⁶¹ reports an abscess of the liver with positive Widal reaction in dilution of 1 to 100. At the autopsy the findings excluded typhoid. The positive Widal reaction was attributed to the bile in the blood. Libman⁶² claims that the presence of jaundice, leading to a positive Widal reaction, is far from being convincing, as no effort has been made by bacteriologic examinations to determine whether or not typhoid bacilli were present in the gallbladder, feces or urine. Even with dilutions of 1 to 1 he had not obtained any characteristic reaction. In only 4 cases had he obtained a positive Widal reaction in the presence of jaundice.

Koenigstein,⁶³ using mixed cultures of *Bacillus typhosus*, colon bacillus and cholera spirillum with gall (taken from cadavers under sterile precautions) in dilutions of 1 to 10, to 1 to 100, found that in 21 tests there was no positive agglutination reaction; in 2 a partial reaction occurred. He injected 2 dogs with small

amounts of a hemolytic poison which resulted in the production of icterus. The serum before the jaundice developed gave a negative reaction in one dog, while in the second animal a positive reaction occurred in dilution of 1 to 10. The results remained the same after the development of jaundice. Tests made with the serum from patients affected with icterus gave negative results in 7 cases, using the typhoid bacillus. In 1 case agglutination of the colon bacillus was obtained.

Cantani⁶⁴ reports experiments to determine the agglutinating power of bile from normal animals and from those immunized against different bacteria. Bile from normal dogs, guineapigs, oxen and rabbits did not agglutinate *Bacillus coli communis*, *Bacillus typhosus*, *Bacillus influenzae*, staphylococci and streptococci. The bile from animals inoculated with these organisms failed to cause agglutination during the stage of acute infection. On the other hand, when bile from animals highly immunized against a specific organism was used, agglutination occurred rapidly and in high dilutions. The agglutinating power of the bile never exceeded or even reached that of the serum. From these observations the author concludes that if agglutinins are present in the serum in small amount they do not appear in the bile, and when in great quantity in the blood, they may then pass over into the bile.

Pneumococcus.—Rosenow⁶⁵ obtained agglutination with the pneumococcus in 77 out of 83 cases of pneumonia (croupous). Ludwig Jehle,⁶⁶ in 6 cases of pneumonia, came to the conclusion that in all the cases that end by crisis there was present a relatively high degree of agglutinating power in the serum. The power of the agglutination appears at the beginning of the disease and remains to the onset of the crisis. After crisis there is a rapid diminution in the agglutinating power, so that in 48 hours it is present only to a slight degree and in 4 days has entirely disappeared. He suggests that the test may be of diagnostic value in the early stages of pneumonia in doubtful cases. Huber⁶⁷ studied the agglutination of the pneumococcus with the serum of patients having pneumonia. The reaction could be obtained about the fifth day and remained until the crisis.

Tuberculosis.—Arloing and Courmont, in 191 clinically tuberculous patients, obtained a positive agglutination in 87.9%, 12.1% did not give the reaction. Of 130 clinically nontuberculous, 34.6% reacted, 85.4% did not. Of 41 healthy individuals 26.8% reacted, 73.2% did not. Loeb personally examined 52 cases in which the technic of Arloing and Courmont was followed. His results are as follows: 1. Cases in which blood-serums were used: (a) Nontuberculous, 2+ (100%), 0—. 2. Cases in which serous effusions were employed: (a) Nontuberculous, 6+ (30%), 14— (70%); (b) tuberculous, 12+ (72%), 4— (27%). In 15 cases of pulmonary tuberculosis most of them with bacilli in the sputum, 13 reacted and 2 did not (Lagriffoul). Four of the former were quite cachectic, of these 2 gave the reaction while in the other 2 the reaction was negative. In 5 cases of surgical tuberculosis, all reacted. In 10 cases of pleural effusion all were positive with blood-serum. In 5 cases the serum of the effusion was used and 4 reacted positively and 1 negatively. In 1 case the serous fluid was negative and the blood-serum positive.

Lagriffoul and Pages⁶⁸ claim that the serum of a newborn child of a tuberculous mother does not generally agglutinate the tubercle bacillus. If the agglutinative substance exists in abundance in the blood of the mother a certain quantity may enter the fetal organism.

Marchetti and Stefanelli⁶⁹ conclude from researches in tuberculosis that the serum reaction, applied according to the method of Arloing and Courmont, is positive within the first 6 hours in 43% of cases. In incipient or light cases it gives positive results in 88%. In cases of lupus the reaction was negative, as it was in 9 cases out of 10 in which no clinical symptoms of tuberculosis

were present. It should be relied upon as a test only when the reaction occurs during the first 6 hours, as in cases other than tuberculosis the reaction may take place after this time.

Dysentery.—Wollstein⁷⁰ found the Shiga bacillus in 39 out of 114 cases of summer diarrhea of infants. The organisms reacted in 21 cases to the Flexner (Manila) serum in dilutions of from 1 to 50, and 1 to 3,000; while Shiga serum gave the agglutination test in dilutions up to 1 to 200. The serum reaction is uncertain during the first week, frequently positive after the sixth day, but may be absent for 2 weeks. It cannot be relied upon for early diagnostic purposes in infants and young children.

Rosenthal,⁷¹ in 30 cases of dysentery occurring in Moscow, found the reaction absent during the first week, strong from the tenth to twelfth days, and less intense after the fourth week. Fifty-two days was the latest time in which he was able to obtain an agglutination.

Strong⁷² isolated a bacillus from patients with dysentery in Manila and tested the serum of 100 individuals, some of whom were suffering from various disorders. In 2 a previous history of dysentery was obtained, and 12 were healthy. In all these cases a dilution of 1 to 10 was employed and a time limit of 30 minutes given. A positive reaction occurred in a surgical case and a partial reaction in a specimen of normal blood. Leonard Rogers⁷³ found in cases of dysentery that the serum reaction was present from the sixth day on, but least marked under 10 days.

Duval and Bassett⁷⁴ in 43 typical cases of summer diarrhea in infants succeeded in isolating *Bacillus dysenteriae* (Shiga). The organisms were agglutinated by the blood-serum of patients from whom they were secured, the serum of other infants suffering with summer diarrhea, the serum of patients with acute dysentery, and with antidyenteric immune serum, but not with the blood-serum of healthy children.

Park and Dunham⁷⁵ examined 22 cases of dysentery occurring in different localities and obtained a positive agglutination reaction in 12 cases in dilutions of 1 to 50.

Doerr⁷⁶ in an epidemic of dysentery occurring in an Austrian town (Bruck), observed 168 cases. The bacillus isolated by him was agglutinated always by the serum of convalescents from the disease in dilutions of 1 to 50; some dilutions were used 1 to 200. The serums of individuals from whom the bacilli were isolated did not seem to agglutinate the bacilli any more or less than heterologous serums.

Lawrence B. Pilsbury⁷⁷ in an article upon the agglutination of dysentery bacilli by the blood of noninfected persons, examined 114 cases of diseases other than dysentery. He obtained a positive agglutinating reaction varying from "complete" to "slight" with the bacillus of Shiga in 108 cases in dilutions of 1 to 10; in 93 cases in dilutions of 1 to 20; in 71 cases in dilutions of 1 to 50; and in 29 cases in dilutions of 1 to 100. With Flexner's bacillus agglutination occurred in 93 cases in dilutions of 1 to 10; in 72 cases 1 to 20 dilution, in 33 cases dilution 1 to 50, and in 15 cases with dilutions of 1 to 100. The term "complete" was applied only to those reactions in which no free bacilli were seen and the clumps were large; "good" was applied to those reactions where small clumps occurred and a few free bacilli. This reaction was especially seen in dilutions of 1 to 20. "Fair" agglutination was applied to those showing fairly good clumps, and when a great many free bacilli retained their Brownian movement to a considerable degree. A "slight" reaction implied one which showed any uniform grouping, however little, well scattered over the field. His conclusions are as follow: 1. That the serum of nondysenteric adult patients does agglutinate the Shiga and acid type (Flexner) bacilli frequently in a dilution of 1 to 20 and occasionally in a dilution as high as 1 to 100. 2. That this agglutinating

power is wanting in the blood of nondysenteric young infants (under one year), rarely being present even in a 1 to 10 dilution. 3. That there are certain differences in agglutinating capability between the Shiga and acid type (Flexner) bacilli, the former in these tests, clumping more readily than the latter. 4. That a decided and prompt reaction, under two hours, with *Bacillus dysenteriae* in dilutions of 1 to 20 or higher in young subjects (under 1 year) and 1 to 50 or higher in older persons who have not recently suffered from chronic or subacute intestinal disease, is probably pathognomonic of acute epidemic dysentery.

Flexner⁷⁸ claims that the serum reactions of cases of dysentery are of the greatest importance, indicating a close relationship between the bacilli from Japan, Manila, Porto Rico and Germany and rendering probable the identity of the epidemic dysentery of this country with that of the East and Germany. S. Ito⁷⁹ has isolated a bacillus from a peculiar form of dysentery in Japan, which organism resembles the colon bacillus. The organism was agglutinated by the serum of patients recovering from the disease, while the serum of normal individuals or of those who had suffered with dysentery or acute enterocolitis had no effect. The serum of patients recovering from the disease did not cause clumping of the dysentery, colon or typhoid group of organisms.

Jürgens,⁸⁰ in a garrison epidemic of dysentery, comprising 26 cases, isolated from the feces a bacillus resembling that described by Kruse. It differed, however, from the latter organism in its forming acid on mannite agar, and resembled more closely Flexner's bacillus. It was agglutinated by the serum of the patients in dilution of 1 to 100 up to 1 to 500, and even higher, while no agglutination occurred with the bacillus of Kruse.

Hewlett⁸¹ tested a number of cases of dysentery for the agglutination reaction upon a strain of *Bacillus dysenteriae* obtained from Dr. Flexner. All the cases, with one exception, failed to give the reaction, while 2 or 3 cases of other diseases gave the reaction. The case of dysentery which reacted was one of amebic type, though there may have been a double infection. Two fresh cultures of *B. dysenteriae*, a Shiga, and a "Flexner" strain, were used, and of 4 cases of dysentery 3 reacted markedly and the fourth slightly. An amebic case did not react at all. Two cases of asylum dysentery also reacted well. It was noteworthy that these cases reacted with the Flexner strain only and not with the Shiga bacillus.

Hiss and Russell⁸² isolated from a case of enterocolitis in a child an organism that presented many points in common with Shiga's bacillus, but was agglutinated by normal horse serum and antityphoid serum. J. H. M. Knox,⁸³ in a series of cases of infantile diarrhea, from which a bacillus was isolated resembling *B. dysenteriae* (Shiga), obtained a positive agglutination reaction in 10 out of 13 cases during the first week of the disease. "As the reaction persists in the chronic cases for weeks or months, it is in this class of cases that the blood tests may prove useful." Cordes⁸⁴ examined the stools of 51 patients suffering from gastrointestinal diseases. *B. dysenteriae* was found in 26 cases. In 25 the acid mannite type of the bacillus was found; in 1, the alkaline mannite form. Agglutination as high as 1 to 3,000, and 1 to 3,500 was obtained with the bacillus of the acid type in 6 cases. The blood of 45 patients was tested with the Harris and Shiga dysentery bacilli in dilutions of 1 to 40, or 1 to 50, with a positive agglutination in 10 cases.

Bergey,⁸⁵ in an article on the reaction of certain water bacteria with dysentery immune serum, concludes that: 1. The agglutination reaction with dysentery immune serum cannot be relied upon in the differentiation of organisms of *Bacillus dysenteriae* group unless we know the limits of the agglutinating power of the serum employed for the particular organism against which the

animal has been immunized. 2. The normal serum of the horse, rabbit, and dog contains agglutinins in relatively small amounts for a variety of organisms. 3. The immunization of an animal against a particular organism increases not only the agglutinins for that organism, but likewise induces an augmentation of the agglutinins of other organisms which are closely related in their receptor apparatus. Van de Velde⁸⁶ was the first to demonstrate agglutination of streptococci by immune serums. He studied the action of the serum of horses, which were artificially immunized against streptococci (quoted by Weaver⁸⁷). Bordet⁸⁸ observed agglutination reaction occurring between antistreptococcal serum and cultures of *Streptococcus pyogenes*. Salge⁸⁹ found that streptococci isolated from cases of scarlatina were agglutinated by the serum of patients in dilutions up as high as 1 to 500. (Quoted by Weaver.) Wlassjewski⁹⁰ obtained agglutination with streptococci obtained from different sources and an antistreptococcal serum. Serum from a case of puerperal fever agglutinated *Streptococcus pyogenes* in dilutions of 1 to 400.

Moser and Pirquet⁹¹ claim that for streptococci the macroscopic test is more readily done, but the reaction is better observed and the details more evident in the microscopic method. Neither shows an advantage in the constancy of the reaction, both evincing great variations. They injected a horse since the first of the year 1900 with streptococci derived from the heart blood of scarlet fever patients. This serum agglutinated the strain of streptococci injected, microscopically and macroscopically, in dilutions of 1 to 1,000. With one exception, it agglutinated streptococci taken directly from the heart's blood and lymphatic abscesses. The streptococci derived from other sources beside scarlet fever did not agglutinate at 1 to 1,000, but a streptococcus isolated from an empyema gave the reaction in a dilution of 1 to 250. They conclude that streptococci from the blood of scarlet fever patients when cultivated upon artificial media for some time, will agglutinate in an immune serum produced by similar streptococci. They find that agglutination of the streptococcus with the serum of scarlet fever patients occurs in 54% of cases. The agglutination in scarlatina is more marked in severe than in mild cases.

Perkins and Pay⁹² found that some cultures of *Streptococcus pyogenes* isolated from the blood and lesions of variolous patients gave a positive agglutination with the antiserum used in the treatment of variola. The method of Meyer was adopted, in which only those cultures which diffusely clouded bouillon were used. Of 9 cultures tested against the antiserum, only one—and that the one used in the preparation of the serum—was agglutinated by it, while in 2 other cultures there was a feeble reaction, but not conclusive.

H. De Waele and E. Sugg⁹³ isolated a streptococcus from the heart's blood in cadavers dead of variola. This organism was agglutinated by the blood of all patients having variola, and conversely the serum agglutinated any of the streptococci isolated from other cases of smallpox, but not other streptococci, except those which were specific for diseases which the patient passed through. The serum of every vaccinated individual also agglutinated this streptococcus, but less so than after an attack of the disease. The serum of nonvaccinated individuals or of newly-born infants possessed no agglutinating power.

Piasetzka⁹⁴ finds that the antistreptococcal serum of rabbits agglutinates completely homologous streptococci, but that heterologous serum rarely produces a complete reaction, and more often no reaction at all. H. Schiller⁹⁵ points out by experiments that serums which have been produced with virulent and unchanged streptococci agglutinate very promptly all the forms of streptococci. Aronson⁹⁶ has produced a highly valent serum which has brought about agglutination with all forms of streptococci derived from pathologic processes, such as angina,

erysipelas, sepsis, scarlet fever, and acute articular rheumatism. As a result of numerous experiments, Weaver has found that of streptococci cultivated from cases of scarlatina, some are agglutinated by almost all scarlatinal serums, but at dilutions varying from 1 to 60, to 1 to 400, others are agglutinated by the same serums with less constancy and at lower dilutions, and many are not agglutinated at all. Streptococci cultivated from cases of scarlatina are agglutinated by serum from cases of lobar pneumonia and erysipelas, in about the same dilutions as by scarlatinal serums, and in the case of erysipelas at even higher dilutions. The same appears to be true of typhoid serum, so far as limited tests indicate, and to almost the same extent of puerperal fever serum. The agglutination reaction between the streptococci cultivated from cases of scarlatina and the serum from cases of scarlet fever is in no way specific, and cannot be of any value as a means of diagnosis. The effects produced by heat and the slight alteration of reaction of the media serve to emphasize the importance of very exact methods in the study of agglutination phenomena in connection with streptococci, as well as with bacteria in general.

Plague.—Wysokowitz and Zabolotny⁹⁷ state that the agglutinative power of the serum in cases of plague is not manifest during the earliest and most acute stage of the disease. It first appears in the blood about the seventh day of illness, gradually increases until the fourth week, and declines after this period. In cases fatal during the first week of illness they found it absent. Polverini,⁹⁸ in regard to the agglutination reaction in plague, claims that it may not be present in severe cases during the first 10 days of the disease and hence concludes that it is of little value.

In 25 cases of plague Cairns has obtained a positive agglutination reaction in 20 in dilutions of 1 to 10 and 1 to 25. In no case has an undoubted reaction occurred in dilution higher than 1 to 75; quite a number (10) gave the reaction in dilutions of 1 to 50. The agglutinative phenomenon is most marked after the second week of illness, and the agglutinative power, insignificant at the commencement of the illness, progressively increases up to the sixth or seventh week of the disease. It then declines, but may be present in wellmarked cases 4 or 5 months after the primary illness.

Raw⁹⁹ states that the plague commissioners came to the conclusion that the serum diagnosis of plague was of no practical value, inasmuch as while the observation takes at least 20 hours to give pronounced opinion, the clinical features of the disease develop with such rapidity as to leave no doubt of the nature of the disease.

Paratyphoid.—W. P. Johnston¹⁰⁰ reports 4 cases of paratyphoid fever. The serum from 2 of these cases agglutinated the paratyphoid bacillus isolated from the blood. In the other 2 cases the diagnosis was made upon the ability of the patient's serum to agglutinate Gwyn's paracolon bacillus, and the organisms isolated from the other 2 cases. In all 4 cases the Widal test was negative. This report includes Gwyn's case. Of 194 cases of enteric fever in which the agglutination tests were made with the bacillus "O" and Gwyn's paracolon bacillus, the results, except in the 4 cases mentioned, were negative.

Hewlett mentions Achard and Bensaude's¹⁰¹ 2 cases of paratyphoid fever in which the Widal reaction was negative throughout. Agglutination reaction was positive, however, with the bacilli isolated, in 1 case from the urine, and in the other from pus in the right sterno-clavicular articulation. He then reports a case coming under his observation in which the serum of the patient gave a positive reaction (with a bacillus obtained from the blood) in dilution of 1 to 100.

Longcope (quoted by Hewlett) reports a case of paracolon infection in which the serum of the patient gave a reaction in dilution of 1 to 200; with Gwyn's bacillus, at 1 to 500; with the Cushing bacillus, 1 to 200; and "Carlez" bacillus 1 to 20. The serum also agglutinated

the typhoid bacillus in low dilution. The work of Cushing,¹⁰² with the bacillus "O," isolated from a costochondral abscess which was agglutinated by the patient's serum in a dilution of 1 to 800, and that of Schottmüller¹⁰³ with cases similar to those of Gwyn is too well known to require elaboration here. Wells and Scott¹⁰⁴ isolated a bacillus which was agglutinated by the patient's serum in dilutions of from 1 to 40, to 1 to 50,000 in cases of paratyphoid fever. Four Widal reactions were made on different days, and all were negative.

Kurth,¹⁰⁵ in 5 cases of Bremen gastric fever, isolated from the feces of one, and from the urine of another, bacilli which were agglutinated by high dilutions of the serum of 4 of the cases.

Brion and Kayser,¹⁰⁶ Libman,¹⁰⁷ and Hume¹⁰⁸ have each observed cases and isolated organisms that resemble yet differ from the typhoid and colon bacilli, which were agglutinated by the serum of the patients.

DeFeyfer and Kayser¹⁰⁹ report an epidemic of paratyphoid fever. Fourteen cases were observed, and the serum of all the cases agglutinated paratyphoid bacilli of the type "A" and "B" of Schottmüller.

L. F. Jermain¹¹⁰ reports 3 cases of paratyphoid fever, the duration of the illness being 16 days. The Widal reaction was negative in each case, though in 1 a serum reaction was positive with Gwyn's paratyphoid bacillus. Kayser¹¹¹ describes 2 organisms isolated from cases of paratyphoid, 1 belonging to the "paracolon group A," and the other to "group B." He thinks that all cases thought to be typhoid fever should be tested with 3 groups of bacteria—the typhoid bacillus and the 2 groups of paratyphoid organisms. The same writer¹¹² observed 3 patients suffering with paratyphoid fever, the diagnosis being made upon the basis of a specific agglutination in high dilutions (1 to 100 and 1 to 1,000) with Schottmüller's paratyphoid bacillus (type B). Bertrand Smith¹¹³ reports 2 cases of paratyphoid infection with positive agglutination reactions in dilution of 1 to 50 up to 1 to 2,000 with the serum of the individual and with the serum of immunized animals. Walker reports a case of paratyphoid fever in which the Widal reaction was negative.

Colon Bacillus.—LeSage,¹¹⁴ in 40 out of 50 cases of enteritis occurring in infants, isolated *Bacillus coli communis* which was agglutinated by the blood of all the patients.

Johnson and Goodall¹¹⁵ have experimented to ascertain the effect of the action of blood-serum in the different forms of insanity on cultures from mixed strains of *Bacillus coli communis* in order to determine whether by the agglutinins direct evidence could be adduced as to the influence of the colon bacillus in such cases or the indirect evidence of a similar action on the part of other organisms related to the colon bacillus. In all, 25 cases were employed. Good agglutination occurred in 4 out of 5 cases of acute melancholia; 1 out of 3 cases of general paralysis; 1 out of 2 cases of delusional insanity. Partial agglutination appeared in 6 out of 11 cases of acute mania; 1 out of 2 cases of delusional insanity; 1 of alcoholic insanity. No agglutination occurred in 5 cases of mania, 1 of melancholia, 1 of puerperal insanity, 2 of general paralysis, 1 of recurrent mania. Agglutination, therefore, was present in 60% of all cases, in 28% good, and in 30% partial. With control experiments, which were made each time, only 1 showed a slight partial agglutination.

Bruce¹¹⁶ found in the blood in a case of acute mania a short bacillus growing singly, in pairs and chains, which was partially agglutinated by the blood of 5 other patients suffering from acute mania.

Micrococcus melitensis.—Musser and Sailer¹¹⁷ obtained a positive agglutination reaction with *Micrococcus melitensis* in a case of Malta fever. Wright and Smith¹¹⁸ also obtained the same reaction. P. W. B. Smith¹¹⁹ reports a case of Malta fever in an officer, who, after 3 years,

still has irregular attacks, and whose blood reacts with well-marked agglutination reaction in dilution of "1 in 40 and over." W. B. Banister,¹²⁰ in a patient who had been in the Philippines where he had been suffering from a fever thought to be malarial, found that the disease presented the clinical features of Malta fever. Serum reaction with *Micrococcus melitensis* was evidenced by marked agglutination.

In Mediterranean fever Aldridge¹²¹ obtained a positive reaction in 30 of 34 cases with *Micrococcus melitensis*.

Miscellaneous.—Vagades¹²² states that we can sometimes show in the blood of patients recovering from influenza a body that gives rise to agglutination of the influenza bacillus.

Wildbolz¹²³ observed agglutinating bodies in the serum of guineapigs intraperitoneally inoculated with cultures of the gonococcus grown upon serum bouillon; the animals developed emaciation and other symptoms. He tested old cultures of the gonococcus as well as young cultures and found the agglutination reaction positive. In 2 cases of gonorrhea, one of which presented epididymitis and elevation of temperature, no agglutination reaction occurred, while in the second case the serum reacted with a young culture of the gonococcus and not with an old culture. He also found that the serum of normal guineapigs and the serum of man did not give this reaction with the organism.

Lerch¹²⁴ obtained a positive reaction in 1 case of yellow fever with *Bacillus icteroides* in dilution of 1 to 10 and 1 to 40 upon the second day of illness. Archinard and Woodson¹²⁵ claim to have obtained agglutination with the bacillus of Sanarelli in 75% of cases of yellow fever. Reed and Carroll¹²⁶ have shown that the same reaction occurs with the bacillus of hog cholera in a small percentage of cases of yellow fever. Pothier,¹²⁷ in 154 cases of yellow fever, failed to get a positive agglutination test with *Bacillus typhosus*. In 19 cases the serum reaction was tried with *Bacillus icteroides* with slow clumping and without loss of motility in 8 cases.

J. B. Tombleston¹²⁸ during two successive attacks of yellow fever, found a bacillus in his own blood that he recognized in 6 other cases of the disease. The serum of a dog immunized against the bacillus produced agglutination with young agar cultures. Lowenthal¹²⁹ diagnosed relapsing fever during the apyretic interval when parasites are absent from the blood. The specific agglutination was most marked immediately after the paroxysm, and sometimes became appreciable just before the next chill. When patients overcame the infection, the reaction lasted longer and if it persisted for 7 days in sufficient intensity to cause cessation of motility of the organisms in 1 hour, no further relapses ever occurred. Gabritschewsky¹³⁰ found that the blood of a patient who had just recovered from relapsing fever would cause an agglutination of spirilla in a specimen of blood kept in the thermostat for 30 minutes to 1 hour.

Spronck¹³¹ claims that the serum of lepers, in dilutions of 1 to 60 and 1 to 1,000, agglutinates fresh living cultures of the bacillus of Hansen.

In diphtheria the serum test does not at the present day figure in the diagnosis of the disease. The bacilli, however, have been agglutinated by antidiphtheric serum by Delepine,¹³² and by Nicholas and Charrin,¹³³ and others. Schwoner¹³⁴ divides the pseudodiphtheria bacilli into 2 groups. The first group, the Hoffman type of organism, is agglutinated partially with normal serum, and completely with monovalent and polyvalent serum, in dilutions of 1 to 10 to 1 to 2,000. In the second group, comprising those bacilli resembling the xerosis bacillus, only homologous varieties are agglutinated with homologous serum.

In tetanus, usually negative results have been obtained; however, Sabrazes and Rivière¹³⁵ by using cultures in a vacuum, obtained clumping with the serum

of a patient on the eighth day of the disease. Bordet was the first to show that *B. tetani* was agglutinated by serum of normal horses.

Achard and Lannelongue¹³⁶ have obtained positive agglutination reactions with *Proteus vulgaris* and *Proteus mirabilis* in animals immunized against the organism.

Rogers¹³⁷ found that *Oidium albicans* grew feebly in the serum of animals immunized against it and formed in masses at the bottom of the tube.

Achard and Bensaude obtained a positive agglutination reaction in 10 out of 14 cases of cholera in dilutions of 1 to 10 and 1 to 20.

SUMMARY.

In summarizing it will be seen that of 17,280 cases of enteric fever, 16,352 gave positive reactions and 928 did not; positive, 94.6%.

In paratyphoid fever 42 cases have been collated, and in 40 of these, or 95.2%, a positive reaction was obtained.

In tuberculosis 221 cases were enumerated, and of them 194, or 87.7%, gave a positive reaction.

Of 390 cases of bacillary dysentery 313, or 80.2%, responded to the agglutination test.

In the other diseases only a small number have been reported, hence no reasonable estimate can be given of the percentage of reactions obtainable.

APPENDICITIS: ITS RELATION TO PELVIC INFLAMMATIONS.

BY

J. M. BALDY, M.D.,
of Philadelphia.

There seems to be considerable difficulty among surgeons in regard to the status of this subject. Much is written concerning it by men who appear to have a good conception of the underlying conditions, much by men who seem to have a very confused idea, and much by men who apparently have not the faintest idea of that about which they are writing, and whose conclusions are consequently worthless. The subject is complicated in some of its aspects and becomes the more confused as there is a lack of common understanding as to the definite meaning of terms used in the discussion. There is, of course, but one basis on which to consider the relation of these two diseases—the pathologic. I use the expression "two diseases" advisedly, as in spite of all that has been written, I am firmly of the opinion that they are absolutely independent conditions and in no way (except in certain peculiar rare circumstances) related one to the other—either in cause or effect. Pelvic inflammatory disease and appendicitis are both infec-

tious in origin. In the case of pelvic inflammatory disease the source of this infection is from the uterus; in the case of appendicitis, it is from the interior of the vermiform appendix or the intestine.

I do not mean to deny that pelvic inflammatory disease may occur from traumatism, nor that appendicitis may arise from the same cause, but this is true so rarely that I wish to be understood as excluding such from present consideration, in order that we may have a definite and common understanding as to the terms "pelvic inflammatory disease" and "appendicitis" as applied to the relation of these conditions. Otherwise there will be as much confusion in understanding as has occurred in the past. It is definitely understood then that in the use of these terms an infective origin is understood.

It is not an uncommon experience for operators to find on opening the abdomen that both the vermiform appendix and the pelvic organs are bound up in a common mass, and this condition is by no means dependent on an advanced degree of inflammatory process. I have myself seen over 100 such cases. For this reason many surgeons find great difficulty in making a diagnosis between these diseases and both worry themselves and endanger their patients by unnecessary delays in trying to be too refined. The comparatively exact methods of diagnosis of the day are such as to render any extended remarks on this part of the subject superfluous. The diagnosis is fairly easy in the majority of cases and when any serious doubt obtains it rarely fails eventually to be settled in favor of pelvic inflammatory disease. The fact of a doubt existing in the mind of a skilled diagnostician is a strong element pointing to the pelvic origin. After the abdomen has been opened, I have yet to see the first case in which a doubt remained in my mind as to which organ was the cause of the inflammation. If then one has a reasonable cause for doubt, the incision should be made as for pelvic disease, because the chances are largely in favor of this trouble, and if by chance it turns out that an appendicitis exists and that the pelvic inflammation is merely secondary, it is because the colon and vermiform appendix are so low as practically to be lying in the pelvis and can readily be dealt with through the median incision.

Kelly has canvassed the methods of practice of some 50 or 60 of the surgeons of the country in the treatment of the vermiform appendix when the abdomen has been opened for any cause whatever. Some 15 or 20 of these men remove this organ as a routine in the practice of abdominal surgery; a very large proportion of them remove it always, if it is adherent. Kelly himself is among this number. A few remove it only if it is otherwise diseased. The reason given by most writers for removing it, if it is adherent, is that its vitality is lowered and that appendicitis is very liable to follow, or that it is already the seat of appendicitis; in fact, the assumption is that in large numbers of these cases the disease is originally appendicitis, and that the pelvic inflammation is secondary.

I am able to appreciate the reasoning (although not agreeing with them) of the class of surgeons who remove the vermiform appendix as a routine practice as a prophylactic measure, but am unable to follow the reasoning of the class who adopt the practice of removal on the ground that the condition of adhesion implies appendicitis or future danger of this disease. In the first place, 90% to 95% of this mixed class are in origin, cases of pelvic inflammatory disease, and the adhesion of the vermiform appendix is a mere coincidence, due to inflammation of contiguous serum surfaces, as is so commonly the case of adhesion of intestines in pelvic inflammatory diseases. Whoever thinks of confusing these adherent knuckles of intestine (to a pus-tube or a salpingitis) with infective disease of the intestines? And how can the mere denuding of the peritoneal coat (and often only the surface portions of it) of the vermiform

appendix predispose it to a future appendicitis or originate an infective process in its mucous membrane lined cavity? Anyone at all familiar with intraabdominal processes is surely aware of the fact that at the end of a week or two, one of two things has occurred to such a vermiform appendix; the serous membrane is fully reformed, or the organ, at the worst, is bound down or covered over by a film of serous adhesion. The formation of the latter condition is well known to be a favorite way of nature to cure certain mild cases of real appendicitis. Call the conditions what you will, a vermiform appendix so involved emphatically is not appendicitis, and its removal cannot, therefore, be justified on this plea. Its removal for the other causes noted is unnecessary in the vast majority of cases, is adding always a certain element of danger to the operation, and not infrequently is so dangerous as to be absolutely unjustifiable.

The justification of taking the additional risk of infection and loss of time is, of course, closely bound up in the future behavior of these cases, and one must in the long run be governed by experience. Personally, in over 100 such cases I have not found sufficient cause to make me remove the vermiform appendix more than once; and this in spite of the fact that in not a few of them, inflammatory products had invaded the underlying coats of the peritoneum. In no such case have I ever had to reoperate on account of the condition of the vermiform appendix, in none have I found symptoms remaining referable to that organ, and in no case in which for any cause I have had occasion to enter that individual abdomen again, have I failed to find the local repair satisfactory (although I admit such opportunity of proof has been rare). In no case have I known appendicitis to occur subsequently in an appendix I have so treated. I do not wish to convey the impression that an appendicitis could not occur under these conditions as well as under normal conditions, because I can see no reason why it should not. I merely record the fact that it has not done so, and only for the purpose of supporting my position, when I assume that this class of injury does not predispose to a future attack of appendicitis. My experience has led me to differ also with those who hold that appendicitis generates pelvic inflammatory disease or that pelvic inflammatory disease generates appendicitis. The 2 diseases are rarely associated, and only then as a coincidence. I am firmly of the opinion that the one never causes the other. The association we so frequently see is the one disease involving the other organ by the spread of inflammation by contiguity, which spread of inflammation does not carry with it the elements of the original infection. And when the one organ or the other is so involved (simply by reason of anatomic relations) the disease can in no sense be called appendicitis on the one hand nor pelvic inflammatory disease on the other, and in neither case is there sufficient reason in the vast majority of cases for so treating it. The mere deposit, as shown by the microscope, of a few inflammatory products in the walls of the vermiform appendix or in the walls of the fallopian tubes or broad ligaments does not make appendicitis in the one case, nor does it make pelvic inflammatory disease in the other case; call it what else you will.

I would record this one other fact as substantiating the position of the one disease not being a causative factor for the development of the other. In all my experience, I have not seen a single case in which, having found pus in a fallopian tube, I have found pus in the involved vermiform appendix; nor have I found a perforated or gangrenous appendix in such a case. And on the other hand, when having found a perforated or gangrenous vermiform appendix, or one which contained pus, either in its cavity or enclosed in its walls, have I ever noticed pus in a fallopian tube or ovary. Should I discover such a condition it would appear to me (so rare must it be) that the 2 diseases existed as a coin-

cidence independent of each other so far as direct infection from one to the other was concerned. If such was not the case the complications would certainly be of frequent occurrence, much more frequent than is even claimed by the advocates of this theory, because it is so exceedingly common to find this association even to the extent of the contiguous formation of pus. I have not infrequently seen the pelvis full of pus in appendicitis and have just as frequently seen the vermiform appendix form part of the walls of a pelvic abscess due to pelvic inflammatory disease.

RESUSCITATION AFTER APPARENT DEATH IN CHLOROFORM ANESTHESIA: WITH A REPORT OF TWO CASES.*

BY

EMIL KING, M.D.,
of Fulda, Minn.

Reports of deaths during anesthesia are comparatively common. The lethal effect comes so swiftly, is so painful to all those concerned that its causes, prevention and treatment are of importance to every surgeon and physician liable to meet such an occurrence. The discovery of anesthesia marked a grand epoch in medical science, it robbed the surgeon's knife of most of its terrors, it made possible the invasion of all parts of the body and is the cornerstone of the practice of surgery as known today. Soon after its introduction sudden deaths were from time to time reported, and as accidental deaths invariably make a profound impression on the public mind, numberless experiments were made and are being made today to determine their cause and prevention. Our knowledge of this subject is still in a somewhat chaotic condition, yet we may accept the points of agreement and use our best judgment when opinions differ.

A study of the reported cases shows that as a rule collapse came suddenly, apparently without a sign of danger respiration and circulation ceased. In some cases there were undoubtedly danger signals which were not observed. Perhaps with or without good reason an unskilled person acted as anesthetizer, or when this was not the case the attendants were too interested in the operation to watch the patient carefully. Chloroform kills through respiratory paralysis and not through its effect on the heart; this must be considered as thoroughly established and the occasional evidence to the contrary finds its explanation in undiscovered pathologic conditions. Most of the studies in this line were made on animals which were presumably healthy, but as we employ anesthesia in disease and injury, which may modify its action, and are debarred from experimentation on the healthy human body, we cannot rely implicitly on the conclusions made in the laboratory. Yet clinical experience shows that death occurs most often in the apparently robust rather than in the sickly and weak, thus in a way corroborating the evidence presented by animal experimentation. As employed in anesthesia, chloroform powerfully depresses the vasomotor centers; as its effect deepens, the respirations gradually decrease in number and depth until they cease several minutes before final cardiac arrest. Coincident with this there is an enormous fall in the blood-pressure which also has its share in causing the respiratory failure. While its main effect on the circulation is through the vasomotor centers it can hardly be questioned that it also depresses the heart directly and so for purposes of treatment we may assume that in collapse we have to combat failure of both respiration and circulation.

On studying the causes leading to this accident I am led to conclude that overdosage is the most important.

* Presidential address at the sixteenth annual meeting of the Southwestern Minnesota Medical Society, Luverne, Minn., January 14, 1904.

The application of concentrated chloroform vapor causes struggling and holding of the breath, intrathoracic pressure is raised, the lungs are compressed and largely emptied of blood leading to engorgement and congestion of the right heart and venous system. Then several deep respirations are taken, and, if the anesthetic is not removed there is a rush of a mass of blood surcharged with chloroform to the left ventricle and the heart already overloaded, is paralyzed.

An interesting observation on this question of overdosage was made by J. Harris¹ in India. On testing an apparatus designed for the painless killing of animals he found that he could not obtain the lethal effect unless ice was placed in the chambers. With the high temperature prevailing there the air would not hold sufficient of the vapor to cause death. Clinical reports from surgeons in that country are also in accord, chloroform being there considered a very safe anesthetic. Most deaths occur early, often before operative procedure. Lawrie² reports the case of a man who went into collapse 2 minutes and 25 seconds after anesthesia was started; he was restored. A few days later this same man was again placed under chloroform, this time anesthesia was complete in 4 minutes and 35 seconds without untoward effect. The surrounding conditions were identical each time except that the drug was given more slowly the second time and Lawrie himself blames the too rapid administration as the cause of the collapse in the first instance. Overdosage may, therefore, occur through too great concentration of the vapor in the air, too rapid pushing of the drug even when an inhaler which is supposed to deliver a proper mixture is used, and when the administration is continued immediately after the patient holds his breath.

Shock must be considered an etiologic factor. On this point there is much difference of opinion, yet it is an undoubted element of danger. Shock in itself is a vasomotor paralyzant, the arterial pressure is lowered, the skin is moist, there is a fall in temperature, all of which is also true of the effects of chloroform, so we may say shock and deep anesthesia are conditions of prostration in which circulatory depression is a vital factor. Deaths from surgical shock are, of course, much less frequent now than formerly, since anesthesia abolishes pain and guards the central nervous system from receiving impressions of the serious damage done the body. In one of the cases to be reported, this question was of vital importance, and I finally decided to operate if the heart's action became stronger and there was no noticeable failure in the patient as anesthesia became surgical. I was led to try this test on account of a case seen in one of Professor Deaver's clinics years ago. A man was brought in in deep shock from a crushed arm; anesthesia, ether was tried; the heart and other conditions not reacting, operation was deferred, the patient dying later from shock. A point of value in determining the safety of anesthesia in similar cases is the rapid estimation of the hemoglobin percentage by Tallquist's³ method, which is accurate enough for the purpose, and consists of the application of a drop of blood from a puncture to clean white blotting paper, and comparing the stain with a series of test tints. If the hemoglobin is below 30%, operative interference is contraindicated. I do not know of any other rule to guide us, and in most cases other attending circumstances must enter into our judgment.

Loss of body temperature may become an element of danger, vital resistance is certainly lessened as the temperature falls. We have all seen patients thinly dressed, large surfaces covered with cloths wrung out in antiseptic solutions, lying on an iron or glass table in a room barely comfortable to men fully clothed.

Fear has been known to kill. We all realize how hard it is to carry safely through sickness a patient who has made up his mind to die.

Certain conditions of illness also predispose to danger

in chloroform anesthesia. Briefly mentioned they are organic lesions in the heart, brain, and kidneys. With the heart the important point is not the loudness of a murmur, but the state of the muscle itself. So long as there is fair compensation and sound muscle fiber there is little to be apprehended, but if there be fatty degeneration the danger is great. Atheromatous arteries in the brain, and certain tumors and inflammations in this organ become elements of danger. Serious chronic or acute kidney lesions, acute inflammations of the lungs and adenoid growths in the upper air passages all offer contraindications to chloroform anesthesia.

Before discussing the treatment of collapse we will consider briefly its prevention. First in importance is the proper administration of the drug. We are all in sympathy with the thought that only those especially trained in anesthesia should have charge of it. It would certainly add a factor of safety to the patient, relieve the operator of any anxiety on this point and leave him free to devote his entire attention to his work. Unfortunately, many practitioners live far removed from competent help, accidents occur, and conditions arise making immediate operation a necessity. Let those who criticize place themselves in a similar position, and then judge leniently. I will not enter into the preparation of the patient further than to state that he should be warmly dressed, the clothing so arranged that respiration is not impeded, fear be calmed and the stomach be empty. I cannot help believing that in a warm room, 80° F. to 85° F., the anesthetic is safer, surgical shock is lessened, and the return of consciousness is more rapid. The question of inhalers is of some moment. I think, outside of a hospital, the simplest and one of the best methods is to fold a clean handkerchief or small towel 2 or 3 times, wet a small spot in its center, and then hold it 1 to 1½ inches from the patient's mouth and nose. This insures slow administration and lessens the chance of overdosage through insufficient admixture with air. To obtain surgical anesthesia by this method requires from 10 to 15 minutes. I very rarely see asphyxia and struggling. Gauze stretched over a light frame of wire, the chloroform put on drop by drop is perhaps the method most commonly employed. Many ingenious and more or less complicated inhalers are on the market, each designed to regulate the percentage of chloroform vapor and air to a nicety. All are more or less objectionable, being either too complicated, cumbersome, or needing an expert for their use. I have seen cotton stuffed into a glass, a quantity of chloroform poured in and then inverted over the patient's mouth and nose. It is a practice fraught with danger. The patient's position is of importance, and should be horizontal. So many deaths have been reported in the dental chair that one can hardly fail to believe that in many of these cases the head was raised. We know that during anesthesia the blood-pressure is low, the floodgates are open, there is more or less vasomotor palsy. During this condition the blood obeys the law of gravity and flows to the lowest point, and if now the head be too high, how easy for the vital centers to be arrested through cerebral anemia. Struggling indicates asphyxia, and invariably the anesthetic must be removed and several respirations of pure air be permitted. Asphyxia may also be due to sinking of the tongue, which is prevented by supporting the chin, pulling it upward and forward.

Asphyxia is one sign of danger, shallow and irregular breathing, weak and irregular heart and widely dilated pupils are the others. The anesthetizer must, therefore, observe all of these signs most carefully. The color of the face is to some extent an index, venous congestion will darken while in collapse its deathlike pallor if once seen is never forgotten.

Certain drugs judiciously employed may be of great benefit. If the patient is nervous and excited, hypodermics of morphin and atropin are a help; if the heart seems weak, strychnin and spartein are indicated, the

former acting as a powerful respiratory stimulant. Digitalis is the ideal heart stimulant, but on account of the pain and abscesses attending its hypodermic use is not well suited for this purpose; its alkaloids are also so uncertain in potency that they too are unsafe. In spartein we have a drug in its action similar to digitalis and its employment should be more frequent. Experiments by Rosenberg⁴ have shown that chloroform vapor exerts its depressing effects at least partially through the nerve supply of the nasal mucous membrane. To overcome this it has been suggested, by Franz Bruck,⁵ to spray the nose with cocaine solution, and those who advocate and have tried this measure claim it makes anesthesia more pleasant, quicker, and safe.

We will now consider our line of conduct in a case of collapse. It comes like a stroke of lightning out of a clear sky. The most painful impressions received during my work as a physician are connected with the 2 cases here reported. While it is agreed that chloroform practically always kills through respiratory arrest, we nevertheless also have a profoundly depressed circulation; in all cases we must assume that we have a failure of both functions, and the more quickly measures of resuscitation are started the greater our chance of success. Our object is, of course, to restore to activity the respiratory and heart centers, and I consider the plan advocated by Kelly⁶ combines the maneuvers first to be tried in an effective manner. On the first appearance of serious symptoms, suspend the anesthetic and protect the wound, if there be one, with gauze pads. An assistant steps upon the operating table, takes one leg of the patient under each arm, and raises the body until it rests on the shoulders. The head is brought to the edge of the table, where it hangs extended and inclined slightly forward. The clothing of the patient is pulled up to the armpits and the operator practises artificial respiration in the following manner: The open hands are placed on each side of the chest posteriorly; the chest is drawn well forward and outward and held thus for 2 seconds, then the movement is reversed by replacing the hands on the front of the chest and pushing backward and inward, at the same time compressing the heart. By this method we get the benefit of position, the elevation of the extremities will by gravitation drive blood to the anemic brain, the filling and emptying of the chest will remove the excess of chloroform and supply fresh air to the lungs and the compression of the precordial region tends to empty the engorged heart and furnishes a stimulant by mechanical irritation. Artificial respiration may of course be performed by any of the many methods known, and at times direct insufflation, mouth to mouth, with bellows, if such are at hand, or through a tracheotomy, has saved life. Other means are suspension by the feet; or the operator may take the patient upon his back, one leg over each shoulder, and trot around the room, causing succussion of the abdominal viscera, as recommended by Prince.⁷ Our efforts so far failing, we may now resort to tongue traction, known as Laborde's method. This investigator found that the rhythmic pulling forward of the tongue, 18 to 20 times a minute, furnishes a powerful stimulus through mechanical irritation of the glossopharyngeal and superior lingual nerves. Dr. Laborde, with the usual French enthusiasm, wrote a book entitled "A Method of Restoring the Dead," strongly advocating this method in all cases of sudden apparent death in which asphyxia is a factor, and while the test of time has considerably curtailed the claims first made, yet so many cases of success are now on record in which other measures had failed, that it undoubtedly has a distinct value. W. Freudenthal⁸ has brought forward a modification, which consists of tickling the posterior surface of the epiglottis with the index finger. This idea seems very sensible, since we all know that the epiglottis is the most sensitive portion of the respiratory tract. For traction of the tongue, that organ may be grasped with especially de-

signed forceps, hemostats, or with the hand. If the hand be used, it is best to cover the tongue with gauze.

If the Laborde method is a distinct advance in the treatment of asphyxia so also is the König-Maas⁹ method of precordial pressure. The operator faces the patient standing on the left side, places the ball of the thumb of the opened right hand midway between the apex beat and the sternum and presses in the thoracic wall with a quick strong movement at the rate of 30 times a minute. Mass¹⁰ failing to resuscitate a boy who collapsed during a circumcision by the usual methods of artificial respiration and slow precordial compression, became excited and increased the rate of compression to 120 per minute. Signs of life appearing in the contraction of the pupils and faint attempts at respiration the rapid compression was continued for one hour before the patient was saved. The same author has also reported other successful cases. This method practised on the fresh cadaver will drive blood to the brain, a distinct pulse wave can be felt in the carotids and the pupils contract as circulation is established in the iris. It is of course easiest to carry out in the young subject in whom the ribs will bend but it is undoubtedly of value also in adults. J. Prus¹¹ made a series of experiments in which he opened the chest wall and massaged the exposed heart itself. He found the human heart responsive to direct mechanical irritation two hours after death by hanging, and actually restored a man, apparently dead, by this means. He recommends the opening of the chest in from 3 to 9 minutes after chloroform collapse, and though heart suture appears to be a safe surgical procedure, we will probably hesitate until further trials have been made as to its efficacy before resorting to such an extreme measure.

I purposely mention the use of drugs in chloroform collapse last in order to emphasize artificial respiration and precordial pressure, because they are most efficacious and quickly applied, two very material considerations. Of the secondary efforts worthy of trial, venous infusion of normal salt solution is of value. Rein¹² reported in 1895 that for a number of years this had been tried in Russia, especially in Moscow, in cardiac paralysis due to chloroform, with great success. Observations on animals show that this infusion raises the blood-pressure and when the heart was not completely arrested recovery would take place. Infusion of salt solution or other medication is indicated either before arrest of circulation and respiration or after they are at least partially restored. The drugs of any real value are adrenalin, strychnin and digitalis. These may be given intravenously with the salt solution, by acupuncture of the heart and injection directly, or hypodermically. There are others such as amyl nitrite, glonoin, cocaine, caffeine, hydrocyanic acid, ether and alcohol all of which have at times seemed useful but the first 3 mentioned have best stood the test of clinical experience and are most strongly supported by wellknown physiologic action.

The cases of apparent death during chloroform anesthesia occurring in my practice have the following histories:

CASE I.—November 12, 1902, O. L., a large, powerful man, aged 27, railroad brakeman by occupation, slipped and fell under a moving car and sustained a crush of the left leg, the foot hanging by mere shreds of skin. I saw him 35 minutes after the accident; there had been a furious hemorrhage, which his companions had only partially controlled. He was much shocked, delirious, and was crying out in an agony of pain. I first applied a tourniquet to arrest hemorrhage completely, then gave morphin, atropin, and strychnin hypodermically and had him carried to a warm room and surrounded with hot water bottles and wrapped in blankets. After a quarter of an hour a second hypodermic, the same drugs as before, was given, and a quart of saline solution was injected per rectum. Forty minutes from the time he reached the room his condition was distinctly worse, and as he was surely sinking, I decided to try an anesthetic. Ether happened to be unobtainable, so chloroform was of necessity the choice. He took the anesthetic well, the pulse becoming much stronger. I amputated the leg 5 inches above the knee, working rapidly, the flaps were cut by transfixion, the femur had been severed, and I was just attempting

to grasp the femoral artery with a hemostat when the anesthetist, Dr. J. D. Kenedy, a dentist with theoretic and some practical knowledge exclaimed, "the breathing has stopped." On looking up I saw the waxy pallor of death on the patient's face and instantly began Sylvester's method of artificial respiration, which was continued 2 minutes without success. Laborde's tongue traction with tickling of the glottis was then tried for 2 minutes. Listening over the heart a few moments, no sounds could be detected, and I had just exclaimed, "the patient is dead," when heart compression flashed into mind. Compression was at once begun at the rate of about 80 a minute; in a short time color appeared in the face and respiration began. My efforts were continued for about 8 or 9 minutes, when he seemed to have recovered from the collapse. I now tried to tie the femoral artery, and on removing the tourniquet a brisk hemorrhage followed, and again respiration failed. I directed Dr. Kenedy to "compress the heart," had one of the witnesses elevate the right leg, and grasped the ligature on the obliquely cut femoral artery and surrounding veins and religated *en masse*, a few stitches were taken, which with Z. O. adhesive strips held the flaps in place; the usual dressings were applied and the stump was tightly bandaged. The patient was breathing feebly, the radial pulse was barely perceptible when we removed him from the table to the bed. Reaction was very slow, the temperature being subnormal for several days. The operative wound was, of course, infected; the muscles in the stump retracted 5 inches, the patient being 6 feet 3 inches tall, and this in due time left the end of the femur at the edge of the wound. He was then sent to the railway hospital, where a secondary operation was done to shorten the femur, without further accident. He is today in good health and wears an artificial limb. I believe had I deferred operation he would have died in shock, the crush wound being so large that it extended into the knee-joint.

CASE II.—D. B., aged 20, a German-American, was first seen March 23, 1903, and had been in labor for 5 days. I found the fetus in the first position, the head presenting, and the amniotic fluid drained away. The cause of the dystocia was a much enlarged and elongated cervix, which had been dilated to a diameter of 1½ inches. The mother was getting weak, and as the cervix could be dilated so the hand could be pushed through an instrumental delivery was attempted. Following a hypodermic of morphin, atropin, and strychnin, I gave chloroform, and when anesthesia was nearly complete I had to entrust this important detail to the patient's husband, not because I wished to, but because the state of the roads made it impossible to get counsel under 15 hours. I then forcibly dilated the cervix, attempting to overcome its resiliency, which was only partially successful, and which finally prevented me from applying both blades of the forceps. I then did a podalic version, and had just delivered the second arm, when the patient stopped breathing. My attempts at resuscitation were the same as in the first case, everything failing until precordial compression saved the life. It took fully 15 minutes until respiration was voluntary and I could give a hypodermic of strychnin and adrenalin solution, which I had ready for an emergency. Collapse came about 25 minutes after I began to deliver, and it was an hour and 12 minutes later when the head was finally born. The placenta was easily delivered by Credé's method, the uterus contracted well, and the patient had the usual puerperium, doing her own housework after the second week. She is now in the eighth month of her second pregnancy.

This case illustrates the difficulty of making a correct judgment as to operation without counsel, just as my first case raises the question of operating during severe shock. I would gladly have divided responsibility in either case.

November 10, 1902, I made an interesting experiment on a stillborn child. Its mother has a malformed uterus. Twice previously she had to be delivered instrumentally, once by myself, and once by my former colleague, Dr. L. L. Rewalt, for ear and brow presentation; and twice I had delivered her by podalic version on account of transverse position with prolapse of the arm; resulting in 4 living children. On my arrival this last time I found another transverse presentation, with the arm out and the cord in the vagina, still pulsating. The os being fully dilated, I gave the mother chloroform and did a podalic version as on the 2 previous occasions. This time, however, the head could not be readily delivered, on account of the os contracting around the neck, forceps could not be applied, and 10 minutes were lost before the head was born. I tried all the usual methods in attempting to resuscitate the child, slapping, hot and cold water, Shauta's artificial respiration, direct insufflation, and tongue traction, without effect. Finally I began rapid precordial compression, according to Maas, and from complete cardiac arrest I succeeded in getting strong pulsations, which, however, failed in about 30 minutes.

It seems to me this case illustrates the irritating effect on the heart of the König-Maas method. I firmly believe my 2 patients were saved by precordial compression, and they are here reported to attempt to show the efficacy of the method. So many cases of success after

other measures had failed are now on record that we should always give it a faithful trial.

To cover the title of this paper fully would require all of the time at the disposal of this society, it is therefore necessarily incomplete, but in closing, I wish to call attention to the following conclusions:

1. Deep anesthesia is always a condition of danger. Therefore every precaution must be taken to guard against danger.

2. When serious accident occurs we must have ready a well-matured plan of treatment which meets the indication in the best possible manner.

3. Death usually resulting from failure of the vital centers the first indication is their stimulation. Artificial respiration, tongue traction and heart compression should be first tried. The application of cold, ether being poured on the abdomen according to Hare, inversion, suspension and succussion, dilation of the sphincter ani and electricity are worthy of trial if the others fail.

4. Hypodermic injections during the stage of collapse are a waste of time. The arterial pressure being nil there can be no effect from medication unless the injection be into the heart. They may do good before cardiac arrest or after the contractions are resumed, and then the remedies of value are limited to a few.

5. Injections of ether and alcohol in any form are apt to be harmful. Their effect in overdose is so similar to chloroform in their action on the vital centers that we only add to the danger by their use.

6. Mechanical efforts at resuscitation must not be so rough that internal organs are injured. That this is possible is proved by reported cases where the liver was torn, blood found in the pleura and the tongue wounded.

7. Since we cannot know when the molecular changes separating true from seeming death take place our efforts at resuscitation should continue for at least one hour.

Microbes Used in Warfare upon Rats.—A report from Paris describes a new method of exterminating rats and mice. The process was devised by the Pasteur Institute, and use is made of microbes. Scientists recently experimented on a tract of nearly 3,000 acres badly infested with vermin. Four tons of bread and 9 tons of oats were used as bait. These had been treated with a solution in which the microbes were cultivated, and were placed near the holes made by the rodents. The scientists estimated that they killed fully 95% of the rats and mice living in the tract treated. A field of two and a half acres was chosen, and 12,484 Ratholes were counted. These were closed, and 2 days later it was found that 1,304 had been opened. The bait was used, and 8 days later only 37 holes had been opened. Fifteen and 20 rats were frequently found dead in one hole. The Chamber of Deputies has been asked to pass a law requiring farmers to cooperate to exterminate rats with microbes. The Government will furnish the solution. The cost of the "cultures" is 3 cents an acre.

A CASE OF PEMPHIGUS VULGARIS, WITH SOME OBSERVATIONS ON ITS BACTERIOLOGY.*

BY

A. C. EUSTIS, B.S., PH.B., M.D.,
of New Orleans, La.

Assistant Demonstrator of Chemistry, Medical Department of Tulane University; Visiting Physician to Charity Hospital, New Orleans, La.

The rare occurrence of pemphigus in this country, together with the chaotic condition of the literature as to its etiology, is my excuse for offering the report of the following case, observed by me during my service as interne at the Charity Hospital in New Orleans.

E. J., a colored male, aged 55, was admitted to the Charity Hospital, July 4, 1901.

Family History.—His father is unknown. His mother died at the age of 74, of asthma. He has 1 sister living, in good health, and he is the father of 2 healthy children.

Personal History.—He is a native of San Domingo, but has been a resident of New Orleans since he was 3 years of age, and has not left the town since his arrival. For the past 4 years he has been working on the drainage and sewerage systems, as a laborer. When a child he had several severe attacks of rheumatism; the first attack when he was 7 years of age. He denies ever having had any venereal disease, but states that he had double nonsuppurative bubo in 1868. He has never been vaccinated. Had smallpox in 1865. Other than this he had never had any eruption on his skin previous to the present one. He had been living in a camp of laborers, working on the sewerage system of this city, and stated that the camp was free from the disease until a German, who had recently joined them, developed it. It quickly became epidemic, and three of his fellow laborers died, while another lost his eyesight as a result of it. On March 3, 1901, he first noticed a small elevation at the root of the penis, which burned considerably. In 6 hours this developed into a "blister containing clear fluid." On the following day he had several vesicles over the scrotum and some on the inner surfaces of the thighs. From here the eruption spread to the right axilla, the left side of the neck, and right leg. For 2

F., pulse 82, respirations 26; heart and lungs normal, liver and spleen not noticeably enlarged. Mucous membrane of the mouth was healthy, but the conjunctivas were somewhat injected.

The following notes will illustrate the course of the disease:

Second day after admission, temperature 100.2°. The patient complained of intense burning pains in both hands, both feet, and the scrotum. There was no apparent change in the eruption. The patient, however, was apparently much depressed. Examination of the urine showed nothing pathologic; specific gravity, 1.018. His temperature ranged from 100° to 102.5° for 7 days, when it gradually dropped to normal. Rapid convalescence followed.

From the second day after admission he complained of intense burning pain in the palms of both hands and soles of

Photomicrograph No. 2.—Magnified 900 diameters. Agar culture from blood of rabbit.

both feet. Two days later numerous petechias could be seen beneath the epidermis of the palms of the hands and soles of the feet, followed 3 days later by complete desquamation of the epidermis, without any signs of vesicles.

On the second day he had a purulent discharge from the eyes and nostrils, and complained of "sore throat." Examination of the mouth showed several small ulcerations on the buccal mucous membrane, while the pharyngeal mucous membrane presented a uniform redness, with swelling of the tonsils, but no ulcerations.

Several of the lesions coalesced, forming tremendous bullas, measuring in some places 6 inches in diameter. Where the lesions broke there were left exuding surfaces, especially noticeable over the sacrum, axillary regions, and scrotum. Several subsequent crops appeared, which would persist for 2 to 3 days, and then either be absorbed or burst. In some instances crusts formed. On the ninth day he was practically free from any vesicles or bullas, but the entire body was covered with patches of fresh epidermis, which was free from pigment. Urinary examinations made from time to time showed that the specific gravity ranged from 1.011 to 1.025. No albumin was found at any time, and no casts excepting once when the urine contained a few hyaline casts. Excretion of urea was not diminished, and the quantity of urine for 24 hours ranged from 50 oz. to 75 oz. There was no diarrhea at any time. All examinations of the lungs were negative throughout.

Treatment.—Treatment consisted of .32 gm. (5 gr.) of quinin sulfate and strychnin sulfate every 4 hours, with increasing doses of Fowler's solution up to the point of tolerance. Daily baths of warm water containing soda were given, after which the body was dusted with boracic acid. For the burning pain in the hands and feet, poultices of soda were applied with great relief. The arsenic was discontinued on the disappearance of the eruption. He was allowed to get out of bed on the tenth day, and was put upon a tonic of iron, quinin, and strychnin.

He remained in the ward as a "helper" and was free from any signs of the eruption until August 1, when he experienced a burning sensation on the right side of the penis, and examination revealed the presence of a small vesicle. There were no signs of an inflammatory condition of the part and the vesicle was identical with the lesion presented on admission. The following day the contents of this vesicle had been absorbed, but 4 fresh vesicles from $\frac{1}{8}$ inch to $\frac{1}{4}$ inch in diameter could be seen on the penis. He was again put on .24 cc. (4 m.) doses of Fowler's solution every 4 hours, increased each day, and with the exception of a few small vesicles on the thigh and abdomen,

Photomicrograph No. 1.—Magnified 900 diameters. Agar culture from patient.

months previous to admission the eruption had been general, the vesicles coming out in crops, and each crop being preceded by intense burning.

Examination at Time of Admission.—Patient was well-nourished and muscular. His entire body was irregularly studded with blebs, ranging in size from that of a pea to that of a hen's egg, universally distributed over the entire body, both on the flexor and extensor surfaces, without any regularity or grouping. The scalp, beard, and pubis, however, were entirely free from lesions. The lesions consisted of multiple bullas, which rose suddenly from sound skin. The contents of the bullas consisted of a clear fluid, and in a majority of instances were quite tense. Several of them could be seen apparently undergoing absorption. The skin was unbroken, temperature 100.5°

* Read at the meeting of the Orleans Parish Medical Society, held January 28, 1904.

which appeared 3 days after the initial one on the penis, there were no subsequent lesions. He was thereafter continued on tonic doses of Fowler's solution and was discharged August 10, with no evidences of ever having had the disease, the fresh epidermis having regained its pigment.

Bacteriologic Experiments.—The day following admission, tubes of agar, bouillon and blood-serum were inoculated under strict aseptic precautions, with the clear fluid from a bleb on the ear. After 24 hours at 37° C., only one small speck could be seen on the blood-serum, while there was apparently no growth on the agar or in the bouillon. At the end of 48 hours, how-

Photograph taken 1 day after admission.

ever, there was a cream-colored growth in the form of rosettes, while a similar growth, less profuse than the former, could be seen on the agar. The bouillon presented a slight cloudiness in the bottom of the tube. Smears stained by Loeffler's solution showed a pure culture of a diplococcus in each instance. It resembled the diplococcus found by Demme, Claessen, Wells, Hadley and Bulloch, and Daehnhardt. It is a slow-growing organism, but grows at room temperature as well as at 37° C. in agar, glycerin agar, bouillon and blood-serum. On solid media the growth is at first white, but in 48 hours develops yellow pigment, imparting a cream-colored tinge to the growth. Occasionally the formation of pigment is excessive and the growth may be orange in color. In bouillon culture a heavy deposit formed in the bottom of the test-tube, the supernatant fluid remaining clear. In shape it resembles the gonococcus, but is larger, ranging in size from $\frac{1}{10}$ of a micron to $\frac{1}{10}$ microns. Hanging drop cultures in bouillon observed from day to day and kept in the incubator at 37° C. showed them occurring almost invariably in pairs, but they may exist in chains of three, four or more. Individual small cocci observed in this manner grow to the size of the larger ones and divide in two, remaining thereafter as diplococci. The larger pairs were seldom found arranged as chains and all were nonmotile. They stain readily with Loeffler's solution, gentian violet, methylene-blue and by Gram's method. Apparently, it occurs in chains of diplococci only when cultivated in bouillon; for, cultures in bouillon, in which they existed in chains, when planted on agar, failed to grow in chains in any instance. This may explain the identity of Gibier's organism referred to below. Cultures in lactose bouillon and glucose bouillon produced no fermentation even after 7 days at 37° C., although there was profuse growth. Likewise, cultures in milk containing litmus failed either to produce fatty acids or to coagulate the milk, contrary to the behavior of the organism found by Wells and reported by Whipple.¹¹

Several animals were injected with cultures of the organism to test its pathogenesis.

EXPERIMENT No. 1.—A male white rabbit weighing 2½ kilos was injected in the marginal vein of the right ear, with

20 m. of a 48-hour bouillon culture of the organism. The back and abdomen of the animal was shaved and he was placed in a small cage for close observation. There was no appearance of an eruption, but its temperature, taken by the rectum on the fourth day after inoculation, was 106.8° F. The temperature was above 105° F. almost constantly, until the tenth day after inoculation, when the animal died, after having lost half a kilo in weight. An autopsy, held 2 hours after death, showed the lungs congested in spots, heart normal, liver normal, spleen congested, kidneys slightly congested, large intestine normal, while the small intestine showed several areas of localized inflammation, together with several small superficial ulcers. The stomach presented 1 ulcer about half an inch in diameter, at the cardiac end, which had penetrated to the external coat of the organ, with another smaller ulceration not far from the first. Specimens of the organs were mounted and stained and the diplococcus was found in the alveolus of the lungs, in the kidney and in the spleen. Unfortunately the mounted specimens of the ulcers in the stomach and intestines were lost and were not examined.

On the seventh day (i. e., 3 days previous to death) several minims of blood were withdrawn with a sterile hypodermic syringe from the marginal vein of the left ear. The blood was dropped into sterile bouillon and plate cultures on glycerin agar made from this. After repeated plating, a pure culture of the original organism was obtained, which was preserved for inoculation into other animals.

EXPERIMENT No. 2.—A young pig, weighing about 35 pounds, was injected subcutaneously in the iliac region with 45 m. of a 24-hour bouillon culture of the organism, obtained from the rabbit. Its temperature, taken daily by rectum, ranged from 103° F. to 104° F. for 6 days. The animal developed 1 pustule on the inner surface of the thigh 4 days after inoculation, but otherwise the inoculation was negative in results; for cultures made from the pustule and plated several times never produced the original organism. The yeast fungus was present to such a great extent and it grew so rapidly that the plates would be covered with it before the diplococcus, if present, could have grown.

EXPERIMENT No. 3.—Another pig, 1 month old, weighing 20 pounds, was injected in the left femoral vein with 1.9 cc. (30 m.) of a 48-hour bouillon culture of the organism obtained from the rabbit. This animal developed only 1 degree of temperature above normal, but on the second day after inoculation it developed a small pustule on the under surface of the neck, while on the fourth day there were several pustules on the inner surface of the right thigh and 1 large pustule on the abdomen. Cultures were again made after very carefully disinfecting the skin, but again I was unable to obtain the diplococcus owing to the yeast fungus.

EXPERIMENT No. 4.—Still another pig, weighing 20 pounds, and from the same litter as pig No. 2, was injected in the left femoral vein with 2.8 cc. (45 m.) of a 24-hour bouillon culture of the organism obtained from the rabbit. Although the animal developed a pustular eruption I was again unable to isolate the original organism.

EXPERIMENT No. 5.—A male white rat was injected in the scrotum and inner surface of the thigh with .6 cc. (10 m.) of a 24-hour bouillon culture from the rabbit. There was apparently no effect on this animal and no signs of an eruption could be seen.

EXPERIMENT No. 6.—A guinea pig weighing 590 gm. was injected in the peritoneal cavity with .9 cc. (15 m.) of a 72-hour bouillon culture obtained from the rabbit. There was very little effect, except a slight loss of appetite and the animal was apparently well until 3 weeks after inoculation, when it emaciated very rapidly and died. Absence from the city pre-

Photograph taken 9 days after admission.

vented my holding an autopsy on this animal, but I feel positive that had I done so I would have recovered the organism.

In referring to the latest literature on the subject one is struck by the various causes, or rather hypothetic causes, assigned to pemphigus therein. I shall not enter into a discussion of these various causes nor shall I try to persuade you that the etiologic factor is to be found in a particular microorganism, but I shall merely mention a few observers who have isolated an organism in the disease.

As early as 1886 Demme² isolated a diplococcus, resembling the gonococcus, from the contents of the bullas of a case of acute pemphigus. Strelitz,³ in 1889, claims to have found two kinds of organisms in the contents of the bullas. His organism, a coccus, sometimes grew white and at other times yellow on solid culture media, and measured from .5 microns to 1.3 microns. Next we find that Almquist⁴ in 9 cases of pemphigus neonatorum found a diplococcus similar to that found by Demme and Strelitz, and he was able, in from 2 to 3 days after inoculation into his forearm, to produce a typical pemphigoid lesion at the site of inoculation. P. de Michelle,⁵ in Italy, in 1891, recovered a similar diplococcus in the pancreas, kidneys, and from the contents of the bullas in a fatal case of acute pemphigus. He found the organism nonpathogenic to 2 guineapigs when injected subcutaneously.

Peter,⁶ in 1896, isolated a diplococcus from the blebs of an infant 8 days old suffering with pemphigus neonatorum, and in addition was able to isolate it from the mother's milk. In the same year, Whipham,⁷ in England, reported the finding of a diplococcus in 2 cases of acute pemphigus, measuring from .8 micron to 1.5 microns, and which induced death in 4 to 8 days when inoculated into mice and guineapigs. Pernet,¹² Bulloch,⁸ Claessen,⁹ Hadley and Bulloch,¹⁰ Wells,¹¹ and Daehnhardt have all isolated a diplococcus.

Paul Gibier,¹ on the other hand, isolated a beaded organism, and Hamburger and Kubel¹³ have found a bacillus.

CONCLUSIONS.

1. In cases of pemphigus a diplococcus can be isolated from the contents of the bullas.
2. This diplococcus when injected intravenously into the rabbit will cause death.
3. A diplococcus removed from the blood of the rabbit and identical with that obtained from a case of pemphigus vulgaris, when injected into the pig (*Sus scrofa*) produces a pustular eruption in the latter animal, attended with mild constitutional disturbances.
4. Arsenic is the main remedy to be relied upon in the treatment of pemphigus vulgaris.

Before closing I wish to thank Dr. O. L. Pothier, pathologist of the Charity Hospital, for his ever ready advice and assistance in the bacteriologic work; Dr. E. D. Fenner, at that time first assistant house surgeon of the Charity Hospital, under whose direction the patient was treated; Dr. Ralph Hopkins, visiting dermatologist, for his aid in arriving at a diagnosis, and Prof. R. Matas for the use of his library and for his kind aid in securing the literature upon the subject.

BLOOD IRON.

BY

EDWARD T. WILLIAMS, M.D.,

of Boston, Mass.

Iron is a universal element. It is found in the heavenly bodies and widely distributed throughout the earth. It is an essential constituent of animals and plants, and occurs in small proportions in sea-water and mineral springs.

Metallic iron is insoluble in water, but combines chemically with oxygen to form 2 principal oxids, the green or protoxid (FeO), and the red or sesquioxid (Fe₂O₃). Both these oxids are insoluble in pure water, but combine with acids to form 2 distinct series of salts, the protosalts and sesquisalts, which are for the most part soluble. The protosalts, which contain the most iron, are as a rule bluish-green in color, while the sesquisalts are mostly reddish-yellow.¹ There are of course exceptions to this rule.

Metallic iron, as has been said, is insoluble in pure water, but water containing carbonic acid, as all natural waters do, attacks it and converts it into carbonate of the protoxid of iron, which is soluble in carbonic acid water and forms the effective constituent of all chalybeate waters. Under exposure to oxygen the protocarbonate decomposes and changes into the red sesquioxid, a reaction witnessed every day in the formation of iron rust.

The chemistry of the common compounds of iron is sufficiently treated in the books and need not be considered here. There is also a vast number of medicinal compounds prepared for therapeutic purposes, but, as they are all converted into chlorids by the gastric juice, there is really no very great choice between them, as chemiscience and clinical experience abundantly prove.²

The iron albuminoids are a more difficult study. It is well known that soluble preparations of iron will, under certain circumstances, combine with soluble albuminoids to form soluble compounds. This occurs naturally in the human stomach and may be imitated artificially outside the body. If an indifferent iron salt and a watery solution of egg albumen be digested with hydrochloric acid a neutral compound is formed of soluble albuminized iron. In this process the acid is decomposed and the chlorin set free, the combined iron being left behind in the condition of a sesquioxid.

An iron peptone may be prepared in a similar way by adding a little pepsin to the hydrochloric acid.

The same reactions take place under similar conditions in the human stomach, whence the products are naturally carried into the blood and tissues.

Organic iron is found in the muscles, liver, bone marrow, and spleen.³ It is said to be an essential constituent of all nuclei. It may have some part in the polar actions of cells. It forms nearly half a hundredth (.42%) of the substance of the red blood-corpuscles.

This substance, popularly called hemoglobin, has not yet been fully analyzed. It consists of an albuminoid, with 4% of iron pigment, and a minute proportion of salts in organic combination. The exact condition of the iron is unknown. It is known, however, that there are 2 forms of hemoglobin, the oxidized and deoxidized. The former is peculiar to the arterial blood, the latter to the venous blood. They differ in color, the former being bright red, the latter bluish. They give different spectrums. From these facts it appears that hemoglobin is a variable and unstable compound. It is constantly passing from a state of oxidation to a state of deoxidation, and from

a state of deoxidation back again into a state of oxidation. The oxidizing process takes place in the lungs under exposure to the air, the deoxidizing process takes place in the systemic capillaries under exposure to the products of the destructive metabolism of the tissues. It is well known that such products have a deoxidizing effect on the sesquioxid of iron and its salts.⁴ The carbon, hydrogen and nitrogen bodies are breaking up and appropriating oxygen from all available sources. Hence we may infer that the iron in oxidized hemoglobin is in the form of the sesquioxid or some of its salts, while that in deoxidized hemoglobin is the protoxid or its carbonate. Von Liebig and Bunge say the latter. This accounts perfectly for the color change, and all the connected phenomena. It explains the respiratory function of the red cells and their agency in the production of animal heat. It would be gratifying, of course, if we had an absolutely accurate knowledge of all the components of hemoglobin. At present we must content ourselves with the closest possible approximation to the truth, which is, I believe, pretty nearly as I have stated it. I am aware that my conclusions are somewhat at variance with those of Bunge and others, but this is not a question of authority, but of plain deduction from admitted facts.

MULTIPLE MYELOMA.¹

BY

GEORGE F. ZINNINGER, M.D.,

of Canton, Ohio.

Cases of which the following is a type are of sufficient rarity to warrant me in placing it on record even if it can be but incompletely reported owing to incomplete clinical as well as anatomic data. On May 21, 1902, I was called in consultation with Dr. H. A. Myers (through whose courtesy I report the case) to see the patient for the purpose of making a diagnosis. The case is as follows:

Mr. B., aged 75, a farmer, of good antecedents. Nothing in the family or past history has any bearing on the case. He had unusual health and vigor and had been a hard worker all his life. His present illness dated back to December, 1901, at which time he fell, striking the sacral region on the hard ground. The fall was quite severe, the patient being unable to walk for several weeks, no fracture however, was sustained. From this time on he began to decline in health and strength. Beside his gradual loss of strength he began suffering with a slight pain in the left inguinal region, associated with gaseous distention of the bowels. He was much relieved after a bowel evacuation. There was also an increasing constipation demanding large doses of cathartics or enemas. There was also manifested a vesical irritability, the patient passing urine rather frequently; it was often distinctly bloody.

Physical Examination.—Patient 5 feet, 6 inches in height, rather emaciated, skin pale, a characteristic straw color, conjunctivas clear and pearly, mucous membrane pale. Pulse 70, temperature 98°. Vessel walls of radial, temporal and tibial arteries were hard and beaded. Nothing further was noted externally, no glandular enlargement. Lungs were entirely negative. Heart, apex least feeble to touch in fifth interspace, 3 cm. within the nipple line. A loud blowing systolic murmur could be heard most distinctly over the apex and was well transmitted toward the axilla. No murmur was heard over the base of the heart except as transmitted from the mitral area. Nothing abnormal was elicited on examination of the abdomen. Sounding the bladder failed to reveal the presence of stone. Prostate was small and hard to the palpating finger. Digital examination revealed high up in the hollow of the sacrum a solid, apparently bony mass, which could be just

reached by the examining finger, it was not attached to the bowel.

A clinical diagnosis of general arteriosclerosis, calcification of mitral valve (there was absolutely no signs or symptoms of insufficiency), and malignant neoplasm, most probably osteosarcoma of the sacrum, was made.¹

There was nothing of importance in the subsequent history of the case, except that on September 25 Dr. Myers detected the presence of an additional tumor the size of a walnut, involving the anterior third of the right clavicle; at this time the tumor was very hard, but it soon grew soft, producing solution of bony continuity. The patient declined gradually, death occurring October 25, 1902.

Autopsy.—Mr. B., aged 75, body 5 feet 6 inches in length, very much emaciated. Nothing was noted externally except that in the anterior third of the right clavicle there was a soft tumor, producing solution of bony continuity. There was also on the right arm a postmortem wound produced in embalming the body (the body had been embalmed with a fluid of secret formula, of which formalin was unmistakably the chief ingredient, and in subsequent descriptions this factor must be reckoned with). The pericardial sac contained no fluid. The heart was about normal size, no excentric hypertrophy; tricuspid and pulmonary valves delicate, mitral valve thickened, being heavily calcified but competent.

Lungs were large, dry, crepitant throughout, and showing a slight degree of emphysema. Liver, spleen, pancreas, and stomach were apparently normal. Kidneys were of normal size, surface slightly uneven, "patchy" capsule, stripping with difficulty. A few retention cysts were noted. Bladder mucous membrane was pale. The bladder contained no stone, but upon its left lateral wall was found a very vascular papilloma, about the size of a cherry. In the hollow of the sacrum, especially to the left and passing out over the sacroiliac synchondrosis, was found a circular tumor, 10 cm. in diameter and 4 cm. in thickness. It was about half buried in an erosion of the bone which was thrown up in a ledge around the edge of the tumor. The tumor had a mottled red and gray appearance, and was of soft, marrow-like consistency. In the anterior third of the right clavicle was found a tumor about the size of an average walnut, the bone being entirely replaced by it. On the anterior third of the third, fourth, and fifth ribs on the right side were found oblong shaped tumors about twice the width of the ribs, displacing the bone, except a thin shell on the anterior side. These tumors could not be palpated externally, even after our attention had been directed to their presence. They were all of the same general nature and appearance as the sacral tumor, except for a firmer consistency. I am convinced this was due to a better fixing by the embalming fluid.

Histopathologic Examination.—The general characteristics of the tumor are a delicate connective-tissue stroma and large thin-walled vessels and capillaries forming a loose mesh-work in which are loosely placed the characteristic tumor cells. The prevailing cell is large and oval, in some instances angular from mutual compression, sharply circumscribed with excentric nucleus and nucleolus, and of clear, smooth, distinct cytoplasm. It greatly resembles a plasma cell of Unna, but is much larger in size and the nucleus which is found (both single and multiple) is always vesicular. Indeed the number of multinucleated cells found is quite remarkable and as many as 4 distinct nuclei have been found, but more often 2 or 3 only are present, and often instead of being distinct and separate they are polymorphous, being connected by threads of chromatin. A distinct nucleolus is seen in nearly every cell. Besides the characteristic tumor cells, numerous polymorphonuclear leukocytes and nucleated red blood corpuscles are found. Many of the tumor cells contain cell inclusions. The tumor contains a very delicate connective-tissue stroma usually accompanying and supporting a very rich vascular supply. The veins and capillaries are very thin-walled, often only an endothelial layer. They are greatly distended and apparently contain more than the usual number of polymorphonuclear leukocytes. The characteristic tumor cells are in intimate proximity to these capillary spaces.

Wright,² of Boston, holds that the characteristic cell in multiple myeloma is the plasma cell and he speaks of these tumors as plasmoma and to account for their presence assumes that plasma cells are histologic constituents of the bone marrow.

Against this conception is that of McCallum,³ of Baltimore, who after dissecting and studying a case seen by me during life in Dr. Osler's wards at the Johns Hopkins Hospital, concluded that the tumor cell is a derivative from the myelocyte of the bone marrow.

Virchow, in formulating his classification of tumors seems to have anticipated a place for myelomas; but it is doubtful if the type of tumor under consideration really

¹ Subsequently, autopsy showed that that which the examining finger in the rectum palpated was not the tumor, which was beyond reach, but an elevated ledge of bone at the margin of the erosion.

² Contributions to the Science of Medicine by the students of William H. Welch.

³ Journal of Experimental Medicine, Vol. vi, No. 1.

¹ Reported before the Canton Medical Society, Friday, March 4, 1904.

belongs to true tumors or neoplasms, but rather to the group of granulomas.

The points emphasized by Mr. McCallum are: 1. The cells are larger in size than plasma cells. 2. They do not react characteristically to the staining methods, especially to polychrome methylene-blue as do plasma cells. 3. In morphology they more nearly correspond to myelocytes of the bone marrow. 4. The gradual transition of bone marrow into the tumor, the myelocytes gradually merging into the tumor cells. 5. Even though the tumor cells do not show neutrophilic granulation when treated by Ehrlich's method, neither do young myelocytes show such granulation.

Since it is my object merely to place this case on record as one of that rare condition, true multiple myeloma, I will not enter into a discussion of it, but will merely say that a study of my case inclines me to accept McCallum's rather than Wright's conclusions. It is regretted that no blood-count was made during life to determine the presence or absence of myelocytes in the circulating blood or any neutrophilic leukocytosis.

Neither was the urine tested for albumose which has invariably been found when looked for in every reported case, so far as I am aware.

Fresh tumor smears could not be made owing to the very thorough and effectual embalming with formalin.

In conclusion I wish to add that specimens have been submitted to Wm. H. Welch who confirmed the diagnosis of myeloma.

8. Laryngectomy for Cancer. H. H. GERMAIN.

1.—Toxicogenic Germs in Water.—V. C. Vaughan reports the finding of such germs in 30% of 709 samples sent by physicians to the University of Michigan. Ten samples contained no bacteria capable of growth at 38° C. These cannot cause disease. Waters are not condemned which contain no toxigenic germs, nor those containing only a typical colon bacillus or a typical proteus bacillus. A typical colon bacillus is nonmotile, produces indol abundantly, produces acid in milk, coagulates milk within 24 hours and evolves gas from glucose and lactose cultures. It requires repeated plating of cultures made from the heart's blood of the inoculated animal to exclude certain germs. Waters that contain any member of the venosus group or any germ with doubtful characteristics are condemned. The writer has never found a germ that responded to the Widal test. Sixteen years of experience with the methods used has convinced him that they are satisfactory. [H.M.]

2.—See American Medicine, Vol. V, No. 24, p. 945.

3.—Accidental Perforations of the Uterus.—D. S. Fairchild thinks this accident more frequent than reports show in gynecologic work and efforts to produce abortion. The sound and curet cause it most frequently in legitimate practice. When the uterine walls are softened by inflammation or degeneration an instrument will pass so easily into the abdomen that the fact may not be recognized. Even when healthy the tissues may be penetrated with greater facility than is generally supposed. Examinations by the sound are more frequent than they should be, and there are often better means of treatment than by the curet. Perforation by the latter would not be so serious were it not for the associated irrigations by which infection is washed into the abdominal cavity. If infection is mild, treatment by rest and ice may be sufficient. If septic peritonitis threatens, a

vaginal hysterectomy with drainage is indicated. In extensive laceration, the fundus may be delivered through an anterior vaginal incision and sutured. If the accident occurs in curetage preliminary to some operation on the uterus, per vaginam or abdomen, the choice lies between suturing or a hysterectomy, according to indications. If an opening of any considerable size is left, there is danger not only of infection, but of strangulated hernia of the intestine. [H.M.]

4.—The Chemistry of the Medical School.—J. H. Long thinks what has usually been understood as medical chemistry is not what the student needs most. That which prepares for the understanding of the why is more important than the learning of isolated tests. Modern physiologic and pathologic chemistry is based largely on physical and general chemistry, as in the problems of immunity and toxicity, the electrolytic components of the blood, etc. [H.M.]

5.—Tropical Cutaneous Myiasis in Man.—J. L. Adams, Jr., states that cutaneous myiasis in Darien is usually due to the *Dermatobia noxialis*. Man and dog are host by preference. It attacks all who are properly exposed. The white-skinned are more susceptible than the darker races. Incubation covers from 16 to 23 days. Larvas differ in shape according to anatomic location. Grub or larvas, if left alone, will not produce injurious results. Abscess and ulceration are the results of attempted expulsion without proper preliminary treatment. The larva lessens its hold if asphyxiation is brought about by closing the opening in the tumor with adhesive plaster, cotton, and collodion, a postage stamp, tobacco leaf, or other measures. After 24 hours only slight pressure is necessary for expulsion. [H.M.]

6.—Carcinoma of the Lung; Pancreatic Cyst.—W. W. Grant reports two cases of carcinoma of the lung—one recurring after an interval of four years from excision of the primary lesion and having at one time coincident tubercle bacilli; the other seemingly primary. Cases of primary carcinoma of the lungs are rare. Pancreatic cyst is usually due to obstruction by stone. There was no evidence of stone in the case reported. Inflammatory conditions may result in hemorrhage and cyst. Without intelligent clinical history the diet is guess work. The disease is essentially surgical and delay is as dangerous and fatal as in appendicitis. The sac may be dissected out if small; if large, the best treatment is to attach the sac to the parietal peritoneum and drain. [H.M.]

8.—Laryngectomy for Cancer.—H. H. Germain compares the deathrate before 1888 with that since, a difference between 35% and 14.5% with a corresponding fall in the number of recurrences, 11.2% as compared with 30.3%. The improvement is due to methods which avoid sepsis and do away with aspiration pneumonia, to early and more radical operating with regard for the lymphatics. In the case reported the coracoid was left in place and yet there is no dysphagia. The tampon canula is being superseded by the Trendelenburg-Rose position. Primary suture of the pharyngeal and esophageal wounds saves weeks of convalescence, while turning the tracheal stump forward and sewing it in the lower wound angle obviates the necessity of a permanent canula and in a great measure prevents aspiration pneumonia. Rectal feeding is necessary for a few days, followed by esophageal feeding, then liquid and solid food in the order given. The slit representing the new larynx is formed between the tongue and posterior laryngeal wall. A distinct pseudovoice is developed after some operations. [H.M.]

Boston Medical and Surgical Journal.

March 24, 1904. [Vol. CL, No. 12.]

1. Ultimate Results of Some Gynecologic Operations at Massachusetts General Hospital. RICHARD G. WADSWORTH.
2. Eyestrain Considered as a Factor in Production of Lateral Curvature of Spine (Preliminary Communication.) HENRY W. KILBURN.
3. Supernumerary Breasts and Nipples, with Report and Photograph of a Case. ERNEST BOYEN YOUNG.
4. Ring Bodies in Anemic Blood, Additional Forms. RICHARD C. CABOT.
5. Typhoid Fever in Infancy, with Report of Case Complicated with Meningitis Terminating in Recovery. CHARLES P. SYLVESTER.

1.—Ultimate Results of Some Gynecologic Operations.—R. G. Wadsworth, in summing up results, finds that

out of 53 cases of laceration of cervix and perineum, in 26% there was no relief of symptoms. Curetage for endometritis in 22 cases gave complete symptomatic relief in 45.5% and partial relief in 31.8%, the remaining 22.7% having received no benefit. Ventral fixation for retroversion in 22 cases was anatomically successful in 77.3%, but only 23.5% received satisfactory symptomatic relief. Of 6 cases of Alexander's operation for retroversion, only 16% were cured, 84% having received no benefit. Of 18 cases of procidentia, 11.1% have been entirely relieved, 33.3% partially relieved, while 55.6% have received no benefit. Of 42 cases of hysterectomy for fibroids, 85.7% have shown satisfactory results and of 5 cases of myomectomy, 80% showed symptomatic relief. Of 12 cases of cancer of uterus on whom radical operation was performed, 3 show no sign of recurrence after 4½ years, in 5 cases recurrence and death occurred within 3 years, and 4 cases are still in doubt. [W.K.]

2.—Eyestrain in Lateral Curvature of the Spine.—H. W. Kilburn reports three cases showing connection between eyestrain and spinal curvature. In two of the cases the curvature caused the patients to approach too near their desks, thus increasing their myopia and setting up a vicious circle. In one of the myopic cases there was a hyperphoria of 1.5°, which disappeared when the faulty attitude was corrected, the latter, probably, having been the cause of it. In the other case, the hyperphoria probably caused the tilting of the head and body. In two of the cases there were unsymmetric axes of astigmatism. Relief from eyestrain not only caused marked improvement in attitude, but when the curvature was corrected, the myopia stopped increasing. [H.M.]

4.—Ring Bodies in Anemic Blood.—Richard Cabot says since his first article on the subject of ring bodies he has examined in all 14 cases of pernicious anemia in the active stages, 9 of which (or 64%) showed the presence of rings more or less similar to those previously described. He has also found them in the anemia secondary to lead-poisoning and in lymphatic leukemia. Negative results were obtained in 4 cases of pernicious anemia in the stage of remission, in 10 cases of leukemia (6 of the lymphatic and 4 of the myelogenous type), 9 cases of severe secondary anemia from various causes, and 22 cases of various skin diseases. In the accompanying cuts are shown some forms not previously illustrated and serving to increase, rather than to dissipate, his ignorance in regard to their origin and nature. [A.B.C.]

5.—Typhoid Fever in Infancy.—C. P. Sylvester discusses the disease in infancy in a general way, and reports a case in which the diagnosis might have been meningitis from the increasing severity of the nervous symptoms, had not the mother suffered from typhoid or had not the Widal reaction been persistently sought. The case forces him to believe that the period of incubation may be 39 days, and that the insusceptibility of the infant was overcome only after a long struggle. [H.M.]

1. The Partial Passing of Neurasthenia. CHARLES L. DANA.
2. The Cystoscope: Its Diagnostic Value. A. M. WOSE.
3. Ligation of Lacrimal Canal to Prevent Infection Following Cataract Extraction. ALEX. QUACKENBOSCH.

1.—The Partial Passing of Neurasthenia.—C. L. Dana contends that 50% of so-called neurasthenias and all the hysterias should be classed as prodromal stages, abortive types, or shadowy imitations of the great psychoses, for it is the morbid mind that dominates the situation, not a weak eye-muscle, a poor stomach, a heavy womb, uric acid, arterial sclerosis, or even an exhausted motor nerve cell. There are five types of insanity, precocious dementias, paranoia, manic depressive and melancholia, phrenasthenic psychoses, toxic and exhaustion psychoses, organic psychoses. Neurasthenia proper rarely occurs under 20. What we see then is pseudoneurasthenia of dementia præcox or dementia præcox itself; slight attacks of recurrent melancholia or manic depressive insanity; or some early development of a phrenasthenia showing itself in chronic headache, spinal irritation, hysterical seizures, fears, and obsessions. Depressive forms of neurasthenia with symptoms of exhaustion and retardation of thought without adequate cause or many bodily symptoms are forms of manic depressive insanity. Neurasthenia in the luetic is often, not always, a pre-

cursor of paresis. Treatment should be directed to the mind rather than the body. [H.M.]

2.—Diagnostic Value of the Cystoscope.—A. M. Wose rehearses the evolution of the cystoscope up to the perfection of the modern instrument. The cystoscopic picture of the normal bladder appears strikingly pale, whereas the mucous membrane after a suprapubic cystotomy is usually dark red in color. At the base of the bladder one finds the ureteral openings, which are often in diseases of the pelvis of the kidney or the kidneys, reddened, swollen and edematous. In renal hematuria or pyuria the blood or pus can be detected coming from the ureter or ureters. The cystoscope is of the greatest aid to differentiate the origin of intermittent hematuria, whether the blood comes from the kidney or its pelvis, the bladder, prostate or urethra. In the male a question of import, many times, is the contour and relation of the prostate gland. The cystoscope gives positive evidence in hypertrophic conditions of the median or lateral lobes. There is a comparable value between the permeability of the kidneys and the catheterization of the ureters. This value is in the phloridzin test, the methylene-blue test and the cryoscopic test, in estimating the functional activity of the kidneys. [A.B.C.]

3.—Ligation of the Lacrimal Canal to Prevent Infection after Cataract Extraction.—Alex. Quackenboss states that infection through the tear-duct is one of the common causes of suppuration following cataract extraction. To overcome this difficulty various means have been employed in cases in which disease of the tear passage exists. He quotes Knapp as advocating ligating the lacrimal canal as a temporary or permanent means of shutting off the infection. Buller has advocated the same. Quackenboss reports in some detail the history of a case in which he performed this operation. Before operating for cataract, the contents of the mucocoele were squeezed out, then a small probe was inserted into the upper punctum and a suture passed around the canal from the inside of the lid out. This was repeated on the lower lid, the cataract was then extracted without difficulty; the usual dressing applied, and changed daily until the sixth day, when it was omitted. The healing process was normal and the operation entirely satisfactory. [A.B.C.]

Medical Record.

April 9, 1904. [Vol. 65, No. 15.]

1. Joseph O'Dwyer, M.D. W. P. NORTHUP.
2. What Shall We Do with the Nervous Woman? WILLIAM C. SEBBERG.
3. The Rectal Segment of the Ureter. BYRON ROBINSON.
4. The Technic of the Removal of One-half of the Thyroid Gland. JOHN G. SHELDON.
5. Two Cases of Splenomedullary Leukemia: Treatment and Recovery. BERTRAM L. BRYANT and HAROLD H. CRANE.

3.—Rectal Segment of the Ureter.—Byron Robinson has dissected and examined a number of subjects, and from these examinations he concludes that in the male, the ureter is more intimately related to the rectum than in the female. The distal ends of the male ureter are imbedded in cellular tissue resting in direct contact with the rectum. The relation of the ureters to the rectum varies according to the resting or distended state of the rectum, vagina, and bladder. Distension of all of these, forces the peritoneum on the bladder a remarkable distance upward, permitting safe abdominal and bladder incisions, to inspect the, or to manipulate the distal peritoneal ureteral ends. In abdominal operations, when the peritoneum is opened the ureter may be recognized close to the rectum by manipulating the cellular tissue between the finger and thumb. In general the ureters and rectum are not parallel in the pelvis, the former following the curve of the lesser pelvic wall, while the latter follows the sacral curve. [A.B.C.]

4.—Technic of Removal of One-half of the Thyroid Gland.—John G. Sheldon describes a method of extirpation of one lobe of the thyroid gland, the method having been first advocated by A. Pearce Gould. Sheldon has employed the method in several instances, which he describes in part as follows: The gland being exposed, the next step is to pass a Kocher's director or one blade of an artery forceps between the trachea and the isthmus. When one clamp has been applied,

a second one is placed close to the first and an incision made between the two clamps. Now turn the isthmus and the lobe to be removed outward and separate the under surface of the gland from the underlying structures with the finger covered with a piece of gauze. The thyroid arteries are exposed as they enter the under surface of the gland. If a transverse incision has been made, the inferior thyroid is first exposed and clamped; if an angular incision has been used, it is easier to expose and clamp the superior thyroid before dealing with the inferior vessel. After the arteries are clamped close to the gland and cut, the removal of the remainder of the lobe is easily accomplished by blunt dissection. The main difficulties in operations on the thyroid are: (1) Hemorrhage; (2) injury to the recurrent laryngeal nerve, and (3) expression of the contents of the gland by manipulation of the organ during the operation, and these are all overcome by this method. [A.B.C.]

5.—Splénomedullary Leukemia.—B. L. Bryant and H. H. Crane report two cases treated by arsenic in one of which the röntgen ray was used. It is a question how much good the ray did. It seemed to hasten matters. The woman had been under treatment but a few days before there was noticeable diminution in the size of the spleen, followed by a severe constitutional reaction, while the second patient improved slowly with no marked disturbance, but the tumor did not begin to disappear until three or four months after the beginning of treatment. [H.M.]

3. On Laboratory Diagnosis. M. P. OVERHOLSER.
4. Skiagraphic Errors: Their Causes, Dangers, and Prevention. (Continued.) LEWIS GREGORY COLE.
5. A Case of Infection with *Bacillus Aerogenes Capsulatus*. S. W. SAPPINGTON.
6. Some Drug and Alcoholic Habitués. SAMUEL B. LYON.

2.—The Tuberculous Patient.—C. P. Ambler says that if destructive processes have progressed in the lung to the point where cavity formation can be detected, great care should be used in advising the patient to leave home. Particularly if high temperature is present, is this true. In such cases, a few weeks' rest in bed at home, preferably in the open air, will see a marked improvement in the general condition. A patient should not be sent away from home in a day or two following hemorrhage. The strongest point for recovery is a full appreciation on the part of the patient of the dangers that are ahead of him. Great care is necessary in selecting a climate for the patient. Hemorrhagic patients should, generally speaking, not go to an altitude of over 3,000 feet. Heart complications should, of course, always receive careful consideration. He says the sanatorium probably offers the greatest hope to the average patient, and is certainly much the better place for those hard to control. If improvement or recovery occurs, every endeavor should be made to remain in the region where such improvement has been brought about. Months should certainly elapse after all signs and symptoms have subsided before the patient should consider the advisability of returning to his old home. [C.A.O.]

5.—A case of infection with *Bacillus aerogenes capsulatus* is reported by S. W. Sappington. The patient, a man of 39, had been drinking heavily and died suddenly a few hours after he was brought to the hospital. At the time of death he had a bowel movement of about 50 cc. of clotted blood. An autopsy was held 12 hours later. The subject was apparently a very large man with tremendous musculature. The phenomenon was explained by palpation, which revealed over the supposedly massive parts subcutaneous crackling. Practically the entire body, with the exception of the feet, showed the subcutaneous tissues to be the seat of marked interstitial emphysema. A large quantity of gas was under pressure in the peritoneal cavity. The stomach was filled with about 2,000 cc. of blood clot, and clotted blood was also found in the small and large bowel. A careful search for the cause of this hemorrhage was futile. The bacteriologic findings are

given in detail. The organism found corresponded morphologically and tinctorially to *Bacillus aerogenes capsulatus*. [C.A.O.]

6.—Drug Habitués.—S. B. Lyon discusses a number of liquor or drug habits treated at Bloomingdale. He says the moral treatment is, as affects permanent results, more important than the medicinal. The therapeutic treatment of drug cases has for years involved the sudden withdrawal of the drug and the substitution of a sustaining agent, such as strychnin and capsicum, upon the theory that a more thorough elimination of the opium from the system is obtained by the copious discharges which occur. The alcohol may be more gradually withdrawn, but a very quick return to the natural conditions is the usual practice. He has found that the systematic bathing relieves the discomfort, itching, etc., which sometimes follows drug withdrawal, and produces a good mental impression. [C.A.O.]

Medical News.

1.—Tuberculosis of the Spinal Cord.—C. L. Dana and J. R. Hunt report a case of progressive amyotrophic lateral sclerosis, upon which was superimposed acute tuberculous infection and also softening of the previously diseased cord. This suggests that the perforating neuroses which accompany some severe cases of myelitis or cord degeneration are really tuberculous phenomena and not primarily hemorrhagic, although there may be associated hemorrhage. The interesting features in the case of pachymeningitis are as follows: The acute onset after exposure to cold; the three months' duration of lancinating pains without other symptoms referable to the spine or nervous system which, in view of the histologic examination, were caused by infiltration and compression of the posterior roots; the very acute onset of the paralysis; the dissociated anesthesia with complete paralysis of motion, which suggested a central lesion of the cord. The spinal cord nerve fibers showed swelling of the sheath and absent or swollen axis cylinders. The dissociation of sensation was not explained by any distinct focus of central softening. [H.M.]

2.—Sanitary Street Car Service.—G. A. Soper discusses the special problem in New York, giving the report of the Merchants' Association. The principal sanitary conclusions are that the sand piles used in lieu of spittoons on the elevated railroad are a great menace to public health. Cuspidors of ample size should be provided. Passengers and train crews should be prohibited from spitting into the streets and on the tracks. Mops, soft brooms, and cloths should be used in cleaning, in order not to raise dust. Sand should never be used except to guard against slipperiness. Cocoa mats on car floors should be prohibited. Catch pans under elevated tracks should be kept clean. Proper attention should be given to the plumbing, ventilation, and warming of stations, and the ventilation and warming of cars. Spaces under the seats should be open, in order that dirt thrown into window casings may be removed. Suitable shelter should be provided at points of transfer, etc. [H.M.]

3.—Early Diagnosis of General Paresis.—W. A. White emphasizes the danger to both patient and family in failure to make a correct diagnosis early. This does not rest primarily on mental symptoms. The dementia manifests itself at first by failure of memory, defective judgment, inability to apply the mind, and failure of moral sense. Symptoms of excitement or depression and delusion may be considered as

unessential accompaniments. The most important physical signs are the oculomotor and tendon-reflex disturbances. They include the Argyll-Robertson pupil, loss of consensual light reflex, loss of sympathetic reflex (dilation of the pupil on stimulating the skin of the neck); 63.6% show this symptom. Knee-jerk may be normal, exaggerated, diminished or lost on one or both sides. There may be slight hesitation and almost unnoticeable defect in the pronunciation of single words and slight tremor about the mouth. [H.M.]

4.—Pulmonary Tuberculosis.—J. J. Walsh points out that the medical profession has not practically applied recent knowledge of the contagiousness of this disease. The physician should ascertain whether the patient has been in contact with others suffering from the disease at home, at school, or at work. Washerwomen and scrub women are especially prone to it. As soon as chronic infection develops anywhere in the body there is disturbance of the pulse long before any sensible variation of temperature is caused. The rate is far from normal and subject to facile and frequent variations. The only way to obtain definite information is to have the patient make a record three times daily for four or five days. The physiologic temperature rhythm does not exceed 1.5° F. daily. The temperature should be taken before 8 a.m., about noon, and about 6 p.m., for three or five days, and if the range is over 1.5° F., there is ample confirmation of suspicions. If at the same time there is cough and loss of weight, there is little doubt of the nature of the disease. [H.M.]

5.—Pathologic Changes in Tissues under the Influence of the Röntgen Rays.—William S. Newcomet discusses at some length the "burns" produced by the röntgen rays. The records of some German authorities go to show that this process closely resembles sunburn, but the effects are much deeper. The general systemic disturbance in these cases is very irregular, but in a general way it follows the course that might be expected from ordinary ulcers. The appearance of the slough differs from that of an ordinary scald, in that it is extremely difficult to remove, and will often cause pain. The explanation is that the slough caused by the röntgen rays is a cell necrosis, and the living and dead cells are intertwined. His conclusions are as follows: (1) That no single form of degeneration is characteristic to the röntgen ray, and that the form of degeneration observed depends upon the tissue exposed and the method of röntgen ray application; (2) it would seem that the effect of the röntgen ray was upon the cell elements in the exposed parts, but why certain normal cells, such as those in hair follicles, etc., should be more susceptible than other tissue is still a question of doubt, but in lieu of the vascular disturbance found by many observers it might be thought that this cause plays an active part. [A.B.C.]

7.—Labor Considered from a Surgical Standpoint.—A. M. Pond asserts that if the study of the history of puerperal sepsis proves anything it is this: In point of technic, the practice of obstetrics is a surgical procedure. The time to save your patient's life is when you are preparing her for, and during confinement, not after the infection has taken place. He summarizes as follows: 1. Success in obstetrics depends wholly upon your ability to secure and retain surgical cleanliness. 2. The same infective agents encountered in surgical practice are the causative agents in producing puerperal complications, and are only successfully combated by the employment of astringent aseptic and antiseptic technic. 3. Refrain from making numerous vaginal examinations, and when done, execute great aseptic care. 4. Do not wait until you are called to the case to make the preparations for confinement. 5. The practice of carrying a confinement pad is dangerous. 6. Sunshine is itself a valuable germicide; do not exclude it. 7. Unless the vaginal discharge is known to contain pyogenic bacteria, the douche is contraindicated. 8. Exert the same surgical technic in dressing the umbilicus that would be demanded in any other fresh wound. 9. Be clean, and be sure that you are clean. [W.K.]

8.—Rubber Cushions for Obstetric Use.—H. A. Kelly gives an illustrated description of the rubber cushion used by him in his obstetric practice. The obstetric cushion is made with a reversible closed sleeve, which hooks up to the rim in such a manner as to catch amnion, blood and placenta, which collected in this pocket can be transported to the bathroom,

weighed and inspected, without the use of any other vessel. For gynecologic and general surgery, it is best to place a sterilized towel between the cushion and the patient. He would also use a sterilized towel or gauze in all obstetric cases. His own practice is to consume from one-half pound to one pound of sterilized absorbent cotton in each obstetric case, unrolling and tearing off a good handful of the cotton at a time and stuffing it between the buttocks below the vulva. When the cotton becomes saturated it is dropped into the receptacle formed by the apron and another piece substituted. Kelly sterilizes the cushions by soaking them for 24 hours in a bichlorid solution 1 to 1000 or stronger. [W.K.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

The Pathologic Manifestations of Filariasis.—If one reviews the various organs that may be attacked by filariasis, it will at once be observed that the lymphatic system pays the highest tribute to the disease. Thrombosis, ruptures, and varices of the lymphatics result, while the serous cavities, such as the peritoneum, vaginal membrane, and pleura are very frequently involved in the process. There is nothing astonishing in the fact that the serous cavities are affected, because both serous and synovial membranes should be considered as lymphatic organs, and histology shows, for example, that the endothelium of the mesentery shows the presence of some lacunas in certain spots, denied, it is true, by some authorities; but in all cases it is quite certain that the leukocytes do penetrate the thin endothelial layer in order to reach the lymphatics or reciprocally, either by traversing the cells or by spreading them apart during their migration. In the peritoneum masses of lymphatic cells are to be found under the endothelium, and pathology has proved the relationship existing between the lymphatic system and the synovial membrane, a relationship so intimate that it is of frequent occurrence to observe fluid collections arising in the knee during the progress of a lymphangitis of the lower limb. The biology of the filaria shows us that the embryos are also found in the blood of subjects infected by the disease, but the reason why emboli and vascular obliteration do not arise, and why it shows an elective predilection for the lymphatic system, can be explained if one considers an all-important factor, namely, the profound influence exercised by hot climates on the entire lymphatic system, an influence that Corre has designated as lymphatexia. It is well known that individuals submitted to a prolonged impression of a hot and damp atmosphere quickly acquire the external attributes of a lymphatic temperament; their flesh becomes soft and colorless and everything in their appearance denotes a general debility of their vital functions. They consequently offer a lessened resistance to the invasion of the principles of infection. Now still more; the blood-pressure and respiratory activity are decreased, there is a tendency toward stasis, especially in the lower limbs and scrotum, which are more passively submitted to the action of pressure, and, from this stasis, the lymphatics which are less resistant suffer more than the others. Thus, it is more than probable that the sluggish lymph current and the lessened resistance produced by the climate in all lymphatic organs explain why the lymphatic system is the favorite one for the lesions produced by the filaria. There is also a latent filariasis, that is to say, one finds in tropical countries individuals enjoying an apparent perfect health, who nevertheless carry embryos of the filaria in their blood. General pathology teaches that the general infections may remain latent and only show their presence when a lessened vital resistance occurs in the individual. The experimental work of Max Schuller in tuberculosis and that of Jaboulay for staphylococic infection and osteomyelitis of young animals is ample proof of this.

One may consequently assume that in the case which now is under consideration, those individuals whose lymphatic system has been able to withstand the climatic influences, or has not become infected, will show no evidence of filariasis, and this will not occur until the general or local state of the individual will permit.

REVIEW OF LITERATURE

Value of the Röntgen Ray in Bronchiectasis.—D. B. King¹ furnishes notes on 20 cases studied by the röntgen ray in addition to other usual methods of examination. In each the endeavor was made to detect the presence or absence of (1) dilated bronchi. In advanced cases where the bronchi were much dilated, as shown by the stethoscope or at autopsy, the röntgen ray failed to reveal their presence; (2) saccular cavities. The röntgen ray failed to reveal such cavities, probably because of the associated fibrosis of the lung; (3) condition of the lung tissue. Fibrosis of the lung was shown by increased intensity of the shadows; (4) foreign bodies. For the detection of foreign bodies in the bronchi, the röntgen rays are undoubtedly of use; (5) action of the diaphragm. This was found to be impaired or obscured, depending upon the degree of change in the lung. King states that the general value of röntgen ray examination in cases of bronchiectasis is sufficient to warrant the röntgen raying of the chest on more than one occasion, though this may give no further information as to the real nature of the case than is furnished by ordinary clinical methods. At present the röntgen rays are of little or no aid in the surgical treatment of bronchiectasis. [A.G.E.]

Ulcerative Endocarditis with Subcutaneous Hemorrhages.—E. Wurdack² reports a fatal case of ulcerative endocarditis, in which peculiar, hemorrhagic changes took place in the skin, especially on the face, but also in other parts of the body. In the face these changes consisted of sharply circumscribed areas of bluish-red coloration, having the form of butterfly wings, one on each cheek. The pathologic process was evidently one of mycotic embolism from the diseased valve, followed by hemorrhage into the skin, and necrosis. [B.K.]

Seventy Cases of Lobar Pneumonia.—E. C. Austin³ reports the series of cases of which 32 males and 6 females recovered and 21 males and 11 females died. Above 50 years of age the prognosis is grave, but even between 60 and 70 years usually some other lesion than pneumonia was found to complicate the condition. In the young the prognosis is good, while in the middle-aged it is dependent upon the other organs, especially the kidneys. In his series, double pneumonia occurred in six cases with one recovery; this one was a teetotaler aged 44. He is of opinion that the pulse-rate is of great value in prognosis. In the series it was very rarely above 120 in those that recovered; in those that died it was very rarely below 120 toward the end of the illness. Diagnosis in a typical case is easy; in an atypical case it is difficult. In seven instances in the series, diagnosis was made only in the postmortem room, and in one instance a diagnosis of pneumonia proved erroneous. Treatment consisted in securing sleep by Dover's powder in the early stages, generally with success. In the latter part of the illness, relief of the heart by means of leeches, strychnia, digitalis, and brandy even proved unsuccessful; benefit from brandy in doses above four ounces was not observed. [A.B.C.]

Tuberculosis Inoculations from Man into Animals.—Fibiger and Jensen⁴ were able to induce tuberculosis of a progressive character five times into calves by inoculating them with tuberculosis material obtained from human beings. In 2 cases the bacilli inoculated proved to be avirulent, in 3 cases only slightly virulent, and in 5 cases virulent. Aside from these experiments they examined the records of 213 autopsies, in 116 of which the patients died of tuberculosis; in 13 of these cases the morbid condition was primary in the intestines or the mesenteric lymph-nodes. Two of the 5 children presenting primary tuberculosis of the intestines, they firmly believe were infected by milk-supply. [J.F.]

Rhythm of the Heart.—James Mackenzie,¹ in an exhaustive article replete with sphygmographic illustrations, concludes that the ventricle can take on the inception of the rhythm, and that when it does so the heart beats regularly. Whenever there is continuous irregularity as distinct from occasional or rhythmic irregularity the ventricle is giving the rhythm; exceptions to this are rare. The cause of the continuous irregularity is to be sought for in the accelerated irritability of the heart muscles, and not in stimulation through the nervous system. Herring's experiments demonstrated that the raising of the ventricular pressure can produce directly the premature contraction of the ventricle. Dilatation and ineffective action of the heart is secondary to irregularity. When the irregularity begins there is uneasiness in the chest, shortness of breath on exertion, and signs of weakness, which increase with each attack; the pulse becomes larger, the veins become engorged, the face dusky, and the lips blue. Treatment should be directed to lessen the irritability of the heart muscles and to protect the heart from increased excitement. Rest in bed is more efficient than drugs. [A.B.C.]

The Portal of Entry of Tuberculosis in Children.—Westenhoeffer,² by inoculating guineapigs, rabbits, and calves subcutaneously in the lumbar region succeeded in producing tuberculosis of the lymph-nodes, in the flanks, in the inguinal region, about the promontory, near the hilum of kidney and liver, also in the mesentery and retroperitoneal lymph-nodes. He found involvement of the spleen, liver, and in some cases, the lungs. Westenhoeffer believes that beside the lymph-vessels which arise in definite regions and empty into regional lymph-nodes, there is another set of lymph-vessels which do not arise in definite regions, but empty into any set of lymph-nodes suitable to them. He says, during the first and second dentition is the only time in life when there exists a physiologic defect in the mucosa of the alimentary tract. This defect in the mucous membrane of the mouth affords an excellent portal of entry for *Bacillus tuberculosis* to reach the cervical, peribronchial, retrosternal, and also the mesenteric lymph-nodes. He believes, nevertheless, that the bronchial nodes may become infected from lung tuberculosis, and the mesenteric lymph-nodes may be affected from the intestines. He maintains that in order to eradicate tuberculosis, the hygienic condition of children must receive greater attention. [J.F.]

Case of Levulose Diabetes.—A new case of levulose diabetes is reported by Lepine and Boulud.³ The patient was a woman of 32 years, and developed the condition during the puerperium. She was unable to assimilate levulose, but utilized glucose well. The disease ran a benign course, and seemed to be cured by total abstinence from levulose. [D.R.]

Antistreptococcic Serum in the Treatment of Scarlet Fever and Diphtheria.—F. Percival Mackie,⁴ after a series of experiments, concludes as follows: (1) Antistreptococcic serum is of distinct value in a certain number of cases of scarlet fever, particularly in those having throat lesions in severe form and at the same time a toxemia; (2) bacteriologic examination will give no sure guide as to the cases in which serum will be beneficial, hence it is advisable to give the serum early and make the bacteriologic examination later; (3) the serum should be given early in the disease, the longer the disease has lasted before the serum is used the less likelihood is there that it will be beneficial; (4) if the first two or three administrations have no effect upon the temperature, its continuation will probably be of no value; (5) the serum is liable to produce a rash; (6) even in those cases in which it does not act there is no evidence that it does harm. In reference to the diphtheria cases he concludes that those cases of diphtheria which present septic symptoms and those in which tracheotomy may be required, may, with advantage, be treated with antistreptococcic serum, in addition to the diphtheria antitoxins. He believes that in all cases of diphtheria where there is evidence of septic infection, as in sloughing in the throat and a high temperature, antistreptococcic serum should be given with the hope that good may result. [A.B.C.]

⁴ The Lancet, February 20, 1904.

Infectious Angina Pectoris.—J. Pawinski¹ describes a form of angina pectoris that is the result of infectious processes. It complicates influenza especially; but also occurs in connection with septic processes, for instance, cryptogenetic sepsis and inflammations of the pharynx, particularly follicular tonsillitis. The following are the characteristics of these forms of stenocardia: 1. Their seat is the anterior portion of the thorax; retrosternal, rather than pericardial pain, radiating in the direction of the cervical and brachial plexuses. 2. They occur in the form of paroxysms, in persons that have never previously had heart disease. 3. The intensity of the pain is as great as that in grave cases of coronary angina pectoris. 4. The pains come on while the patient is in bed. 5. The pain often occurs at the beginning of the disease, and even in the period of incubation. 6. When the infection localizes itself in a particular organ, the pains diminish or disappear. 7. The stenocardia commonly occurs in cases in which the temperature elevation is insignificant, and sometimes when there is complete apyrexia. 8. It is sometimes accompanied with symptoms of cardiac insufficiency. As predisposing causes may be mentioned the neuropathic state, excesses in alcohol and venery, the abuse of tobacco, emotions, strain (physical and intellectual), cold, etc. The prognosis is favorable. As to the pathogenesis, the author believes that it depends upon lesion of the nerves of the cardiac plexus produced by the septic toxins. It may be that at times there is a temporary spasm of the coronary arteries. When the angina persists, it is probable that the lining membrane of the coronary arteries has sustained permanent change. [D.R.]

Hemoglobin in Chronic Heart Disease.—Theodor Schott² treated a series of 120 patients by combined baths and gymnastics. He states that the combined treatment has a tonic action, not only on the heart but on the whole system. The treatment is capable of increasing the formerly depreciated hemoglobin in cases of heart affection be they weakness of the heart muscles, valvular disease, Graves' disease, or chronic myocarditis with or without kidney disease. In some cases the increase was only slight. It was far easier to raise the amount of hemoglobin in young and middle-aged persons than in the elderly. Even though the latter are much improved in a general way by the treatment, there is frequently no change seen in the amount of hemoglobin; in a few instances the amount of hemoglobin was actually diminished. Severe physical overexertion and violent emotional disturbances, especially in febrile disease, rapidly produce a diminution in hemoglobin. Instrument employed was the Dare hemoglobinometer. [A.B.C.]

The Flicker Diagnosticum.—J. Meyer³ instituted a series of investigations utilizing this method of diagnosis. He first tried it upon nine patients that were clearly suffering with typhoid fever, and in guineapigs infected with *Bacillus typhosus*; in a second series the diagnosis was not definite, and in a third the cases were clearly not typhoid fever. From his results he concludes that the method not only gives the same results as the Widal reaction, but also believes it to be more useful to the practising physician. [J.F.]

Some Clinical Aspects of Rheumatic Infections.—Carey Coombs⁴ reports in detail a series of 10 cases, and states that clinically there are certain characteristics of rheumatic infection and its results. Whether the infections be of joints, of heart, or of brain, these characteristics are of two extremes of severity, transient and malignant, and between these extremes a complete gradation of protracted cases in which an imperfect resistance on the part of the infected organ or tissue leads to connective-tissue increase of a prominent and crippling nature. These protracted forms are characterized by more or less frequent exacerbations. The suggestion is that in many cases of rheumatic infection the organism persists in the affected tissue after all obviously inflammatory signs and symptoms have disappeared in a comparatively but not absolutely harmless state, capable of reexaltation of virulence under unfavorable circumstances. To summarize: Clinical observation of rheumatic infection shows (1) a certain similarity of effect, whatever the tissue infected; (2) the capability of such infection to inflict

any degree of damage on the tissue attacked within certain limits; and (3) a tendency on the part of the infecting agent to persist in the affected tissues. [A.B.C.]

Paralysis of the Recurrent Laryngeal Nerve in Mitral Stenosis.—Alexander¹ reports a case of intermittent hoarseness. In a röntgen ray photograph of the thorax he finds the transverse diameter of the heart increased; the picture fails to show a tumor of the mediastinum, aneurysm or enlarged mediastinal glands. Alexander believes the paralysis is due to the pressure of the dilated left auricle, conus arteriosus and pulmonary artery upon the recurrent laryngeal nerve. [J.F.]

Observations on the Movability of the Apex of the Heart.—W. J. Pettus² says that American text-books on physical diagnosis give but scant attention to changes in the position of the apex beat of the heart caused by certain positions of the body. Careful examination of 60 patients by auscultation, percussion, inspection and palpation elicited the following facts: When patients were changed from an upright or prone position to one on the left side the average move in the apex beat was one and one-half inches to the left; with the patient on the right side the apex beat moved one-half inch to the right of the normal position. In eight of the 60 patients the apex moved two inches to the left when the position on that side was assumed. In only three of the series was the movement less than one inch. The conclusion reached from this series of cases is that in examining any patient suspected of having hypertrophy of the heart, the examiner should be careful to have him either sit perfectly erect or lie evenly on his back. [A.G.E.]

The After-effects of Head Injuries.—T. Crisp English,³ in his Hunterian Lectures, has collected the notes of 300 patients whose condition he investigated at some time after their head injury. Of these there were 100 cases of fracture of the skull, examined at an interval of one year or more after the injuries; 100 cases of concussion, cerebral contusion, and laceration without evidence of fracture examined also at intervals not shorter than one year after the injury; and 100 miscellaneous cases other than those included in the first two groups. He states that with our present knowledge of the symptomatology of cerebral injuries it is clear that many of the injuries described as concussion should be described as cerebral contusion or laceration. Some degree of mental impairment though rarely sufficient to be denominated traumatic insanity, occurred in about 10% of the patients. The chief lesson learned was that the great majority of the patients who suffered from head injuries became absolutely well, provided they submitted to the necessary period of mental rest after the injury. Those who suffered from remote consequences were the patients who returned to their business soon after the accident before they had completely recovered. Thus it happens that grave consequences are more liable to follow the slighter forms of concussion than the graver in which proper treatment is enforced. The average interval between the date of the accident and the return to work after simple concussion was 4½ weeks, after cerebral contusion 9½ weeks, after fracture of the skull or cerebral laceration, 13 weeks. [A.B.C.]

The Significance of Black Urine.—A. E. Garrod⁴ names the following conditions in which urine that is black, or becomes black on standing, may be excreted: (1) jaundice, especially when of long standing; (2) hematuria; (3) hemoglobinuria; (4) hematuria; (5) melanotic sarcoma; (6) alkaptonuria; (7) ochronosis; (8) when abundance of indican is present; (9) long-standing pulmonary tuberculosis; (10) after taking certain drugs and articles of diet; (11) certain rare cases of undetermined nature. These varieties are briefly considered in detail, partially as regards points of differentiation and partially from their diagnostic and prognostic significance. The prognosis varies greatly. Melanuria is of the gravest import as signifying the recurrence of melanotic growths in the viscera; an equal degree of blackness of the urine is reached in alkaptonuria, which, so far as known, is a quite harmless condition. [A.G.E.]

Microtia.—W. C. Brailsin¹ reports two cases of this condition, from the practice of Dr. Drury, which he believes to be unique in the fact that they occur in two members of the same family, simulate each other in shape and are on the same side in both instances. The parents are of Jewish descent. The first child was normal in every way. The second had a rudimentary right ear consisting of an oval, smooth growth one-half inch by one-quarter inch in size that contained cartilage and had a slight indentation in the skin. The mother was very much depressed over the condition and declared that she would never give birth to another child. She became pregnant four years later and during gestation worried constantly for fear that the child would be deformed as was the preceding one, although assured that this was hardly a possibility. When the child was born it was found to have a similar deformity of the right ear. Both children are females. [A.G.E.]

EDITORIAL COMMENT

The Uses and Value of Moist Dressings.—The dictum of Von Bergmann that absolute dryness is the best antiseptic has been accepted by most surgeons, and for ordinary operative wounds there can be little question that almost any form of dry dressing will prove satisfactory. The amount of secretion from such clean wounds, made with clean instruments and subject to little traumatism is always very slight and the absorbent qualities of the dressing are not severely taxed in disposing of it. Accidental wounds which are not as certainly clean; wounds necessarily subjected to considerable traumatism during operation, and wounds which are certainly infected at the time they come to the surgeon, offer quite different conditions and the amount of wound secretion is frequently very great. The dryness of the wound in such cases depends upon a highly absorbent property in the dressing used. Noetzel² an assistant in the clinic of Rehn of Frankfort, has recently carried out some interesting experiments to determine the comparative value of moist and dry dressings in cases in which there is a considerable amount of wound secretion. He found that in open muscle wounds of rabbits either dry or moist gauze took up the secretion and anthrax bacilli in an experimental wound so satisfactorily that no disease of the animal experimented upon resulted. The capillary drainage from the moist dressing was much more active than that of the entirely dry dressing of the same kind of gauze, however, so that with the moist gauze the germs which were taken up with the secretion were found in the outermost layers of the dressing as well as all the intermediate layers, while with the dry dressing the bacteria were found only in the lower layers immediately in contact with the wound. Moist bichlorid dressings also were used and the antiseptic was found so effective that neither anthrax bacilli nor ordinary bacteria of the skin showed any growth on cultures made from the gauze. With the more active absorbing property of moist gauze in mind, dressings moistened with mercuric chlorid solution at the time of application were used in the Frankfort City Hospital and were allowed to dry after application. This form of dressing was found most satisfactory in actual practice and the experimental evidence also seems quite convincing. For some time we have been accustomed to use moist dressings in the treatment of infected wounds and have not been dissatisfied with the results obtained in this way. Everyone recognizes the greater absorbent power of moist gauze. It can readily be seen by throwing a dry gauze surgical sponge, and one saturated and then wrung out, into water together: The moist sponge sinks

quite quickly while the dry one will float for some time. With most wounds in which considerable oozing is expected, drainage is only needed for a few hours after operation and if a moist dressing is applied it favors the drainage and by the time the dressing is dry the necessity for drainage probably will have ceased. Any danger from the moisture of the dressing is prevented by saturation with the antiseptic, which also ceases to have any effect when the gauze is thoroughly dry. We believe that this drying out dressing, "austrockenden Verband," as Noetzel has termed it, will be found useful and safe in the treatment of many wounds from which considerable secretion may be expected.

REVIEW OF LITERATURE

Treatment of Fractures and Dislocations.—F. F. Burgard¹ discusses at length fractures of the clavicle, Colles' fracture, Pott's fracture, dislocations of the humerus at the elbow, of the semilunar cartilages of the knee, and discusses fractures in general. He says coaptation should be effected under an anesthetic, and some form of retentive apparatus applied, so that it leaves the seat of fracture either exposed or accessible without disturbing the fractured ends. The apparatus should fix the joint above and the joint below the fracture. On the following day the parts should be gently massaged after the limb has been fixed in the splint. The rubbing is repeated on the day following the first dressing for 10 minutes or 15 minutes, and again on the second day. On the third day the rubbing is followed by passive movement of the small joints beyond the fracture. This combined massage and passive movement of the small joints is persisted in for the next two or three days, at the end of which time an addition is made to the treatment, in that the joint below the fracture is very cautiously moved. Passive motion of the joint above the seat of fracture is deferred till later. Thus, for the first two or three days simple rubbing over the area of fracture alone is done, then from the third to the sixth or seventh days massage is followed by passive movement of the toes or fingers, as the case may be, while to these are added, from the end of the first week, the passive movements of the wrist or ankle, and lastly, of the knee or elbow, by the end of the third week. He insists upon passive motion being made early in case of Colles' fracture. The pain and loss of function which often follow treatment of this fracture are, in many cases, due to deferred passive motion and massage. [A.B.C.]

Spina Bifida.—H. Reineking² reports three cases as a basis of remarks on the operative treatment of this condition. The first was in a child of 16 months who had double spina bifida, hydrocephalus and extremely limited motion in the lower extremities. Aspiration of the larger tumor was practised nine times when infection occurred. Three months later the larger tumor, a pure meningocele, was excised and the smaller one injected with Morton's fluid. Both procedures were entirely successful. The after-history of this case is very instructive. At the age of six the boy was able to walk alone. Now, at the age of 10, he is intellectually rather ahead of other children of his age. The size of his head has not increased in proportion to the rest of his body, although it is still somewhat larger than normal. Case II was one of meningocele in which aspiration was performed as a palliative until the child became strong enough to justify operation; infection, meningitis and death followed the twenty-seventh aspiration. In Case III operation has been refused. Reineking holds that hydrocephalus or paraplegia should not of themselves constitute a contraindication to operation. [A.G.E.]

Treatment of Incontinence of Feces by the Submucous Injection of Paraffin.—Arthur H. Burgess³ reports in detail two cases. The first was a man of 58, who three years previously had undergone two operations for fistula in ano; incontinence of feces resulting. Two subsequent plastic operations failed to relieve the condition. On examination no trace of a sphincter could be discovered. Under anesthesia Burgess

³ The Lancet, March 12, 1904.

injected paraffin in several places into the submucous tissue of the rectum, commencing high up and working toward the anus. In all, at two sittings, a total amount of 52 cc. of paraffin with a melting-point of 111° F. was introduced. He last heard from the patient, nine weeks after the operation, at which time he stated he had had complete control over his motions. The second case was that of a boy of 7, who had suffered from prolapse since infancy. Several operations had failed to relieve the prolapse and the child suffered from fecal incontinence. Burgess first injected only 6 cc. of paraffin, subcutaneously, which prevented a recurrence of the prolapse, but did not control the motions. Subsequently 27 cc. of the paraffin was injected in three successive tiers and this improved the condition materially, but did not completely correct the ill condition. A plastic operation, subsequently, similar to a Tait flap-splitting operation for repair of an incomplete laceration resulted in complete relief to the child. [A.B.C.]

Treatment of Cancer of the Stomach.—G. Gayet¹ discusses at length the treatment of cancer of the stomach by gastroenterostomy with the button of Jaboulay-Lumiere, commonly known of the button of Jaboulay. This is a modification of the Murphy button and appears to do away with some of the objections to that instrument. The weight is diminished, the lumen is larger, it requires no sutures and can be inserted more rapidly. The after-results are claimed to be uniformly satisfactory. Gayet tabulates 100 cases, the great majority of which were done by Jaboulay himself. The mortality, including all cases of death within three weeks after the operation, was 18%. This rate is rapidly decreasing as shown by a mortality of only 7.6% in 1902, and of 6.66% in the first half of 1903. The average length of life of the patients after operation was seven months and the amelioration of symptoms was greater than in cases of anastomosis by suture. The time of operation is comparatively short when this button is employed, the average in the hands of Professor Jaboulay being from 7 to 10 minutes, including suture of the skin. [A.G.E.]

Cleft Palate and Harelip.—Edmund Owen² states that for 20 years it was his practice to operate upon harelip in early infancy, but to postpone the treatment of the cleft palate until the child was 2, 3 or 4 years of age. Following the suggestion of Brophy, he has abandoned this procedure and now operates on the cleft palate at an early age and before operation is performed upon the harelip. A case is reported in which he operated upon a cleft palate when the child was but 3 months old, with entire success. His conclusions are, that serious as the operation on the palate may be, the infant may be expected to survive it. He quotes, without entirely agreeing with Brophy, that the shock following the operation is not so great if performed within the first months as it would be later in childhood. Owen further states that, since the maxillas are closely approximated, the halves of the velum can be stitched together without tension and without the need of interfering with the attachment of the muscles of the soft palate; that, as the approximated halves of the soft bone can be sutured without interference with the muscles of the palate the prospects of securing a natural voice are greatly increased; that, as the maxillas have been brought together in front, the subsequent operation upon the harelip is rendered much easier of performance and a more artistic result is obtainable. [A.B.C.]

Traumatism of Circumflex Nerve in Shoulder-joint Injuries.—F. E. Bunts³ calls attention to this common and serious complication of shoulder-joint dislocations and the medicolegal importance of its recognition. The most frequent lesion appears to be that of contusion or compression of the nerve. The effects of either are frequently aggravated by resulting extravasations and inflammatory exudates. In general the prognosis is not good; a considerable number of patients lose the use of the deltoid muscle. Bunts tabulates 19 cases; in eight the injury followed dislocation; seven resulted from contusion; one from wound of neck; one from stretching; one from pressure of cancerous glands, one no history. In most cases the paralysis has been observed soon after the injury; in Bunts' experience it has been noted when the dressings or

splints were removed in from two to eight weeks. It is desirable to examine for this injury immediately after trauma or after a dislocation has been reduced in order if it is present to make a more serious prognosis. The treatment, in addition to usual means, should include training of the patient by proper gymnastics to develop the synergistic and vicarious actions of muscles other than those supplied by the circumflex in order to preserve function of the arm. [A.G.E.]

Cancer in Australia, with a Specific Treatment Suggested.—G. Clark Adams¹ concludes his article, which he summarizes as follows: 1. Cancer is not due to a bacterial or a parasitic origin. 2. It is a constitutional disease, due to specific or malignant virus originating in the blood, chiefly manifesting itself after 35, and at its greatest virulence between 50 and 60. 3. It may be congenital, and certain forms may be acquired by infection or contagion. 4. The principal factor in the cause is hereditary tendency. 5. The principal exciting factor is prolonged irritation acting on a constitution suffering from an inherited tendency, or which has been developed through want of treatment of one or other of the following diseases in their order of frequency—syphilis, alcoholism, obesity, rheumatism, gout, or tuberculous disease. 6. The principal etiologic factors in the cause are sugar, beer, and alcohol. 7. The principal hygienic factors in the cause are woods and forests, whose dropping foliage decays and causes stagnation of water, also badly formed streets, defective drainage in cities, and the overcrowded, badly housed and poorly fed population of cities. 8. Cancer is a preventable disease, and the absolute cure is only to be found in the means of preventing its exciting cause, and completely removing the same. 9. The sanitary indigenous foliage of the following orders: (a) myrtaceae, (b) laureaceae, and (c) conifers appears to exercise a specific influence in rendering the native born population of the countries where they occur almost immune from malignant diseases other than may be caused by prolonged irritation. 10. A eucalyptol oil obtained by means of a scientific process from various species grown in Australia possesses specific action in arresting the pathologic progress and process of malignant disease. 11. All internal and local treatments of irritative nature should be absolutely avoided, more particularly such local treatments as the röntgen rays and Finsen light, as they are likely to set up secondary conditions around the seat of lesion; far better is the early and prompt removal when the malignant growth is accessible. [A.B.C.]

Tumors of the Thyroid Body with Metastases.—M. Patel² gives a very instructive review of this subject, which in many of its aspects is yet very obscure. It appears to be definitely established, however, that tumors of the thyroid that are clinically benign may give rise to metastases that are malignant as well as to those that, like the parent tumor, are benign. Microscopic examination reveals the true nature of the tumor, if the clinical picture is not decisive. Metastases occur in bones or the lungs. The former involve principally the short and flat bones, as the cranium, maxilla, vertebral column, pelvis, but are also found in the long bones. The size of the goiter does not seem to influence the appearance of secondary growths; the cause lies in the tumor itself, the colloid variety most often undergoing metastasis. Of the 18 cases reported by Patel, 14 were in females, but this is probably due only to the more frequent occurrence of goiter in that sex. Treatment consists in general thyroid administration, removal of all or a part of the goiter, and removal of the metastatic growth. If the secondary tumor possesses malignant characteristics, a radical operation is required; if it be benign more conservative measures will suffice. Abstracts of the 18 personal and collected cases are given in concluding the paper. [A.G.E.]

Influence of Operations on the Course of Diabetes Mellitus.—O. Körner³ has collected and tabulated operations for acute mastoiditis in diabetic patients. He finds that in mild cases of diabetes, the operation may cause a temporary increase in the sugar excretion, but no permanent harm results. The occurrence of coma as a result of the operation is only to be feared when the diabetes is of a severe form, and the urine

gives the diacetic acid reaction. If operation is necessary to save life, it may be performed even in cases of moderate or considerable severity. [B.K.]

TREATMENT

SOLOMON SOLIS COHEN

L. F. APPLEMAN

E. LINDAUER

REVIEW OF LITERATURE

Tallow or Beef Suet.—R. Ortega¹ relates how, by misunderstanding, a tuberculous patient took a quantity daily. His cough and general health improved. The author believes that tallow has a peculiar value in internal medicine, for the reason that it is a fat which adheres to mucous membranes. If heroin or codein, etc., cannot be employed, and no one may be entrusted with chloroform, or other inhalants, at the bedside, tallow by the mouth is a safe and effectual remedy in cough. There are intestinal disorders which benefit by its administration, which may be in caché. [T.H.E.]

Aristochin in Bronchial Asthma.—K. Dresler² found that aristochin produced very quick relief for asthmatics. At first they invariably complained of being worse, but soon after the spasms lost their intensity, the attacks became fewer, the cough and dyspnea disappeared completely after a short time. One man who had been suffering unspeakably for three years, and who had not been relieved by any of the known drugs, was relieved after taking 0.4 gm. (6 gr.) of aristochin three times daily for six weeks. The drug quiets the irritated nervous system of these patients markedly and regulates the cardiac rhythm, also diminishing the heart-beats considerably. It may produce slight transient itching and buzzing in the ears, but otherwise nothing unpleasant has been complained of. [E.L.]

Thiocol in Tuberculosis.—While denying this remedy any specific antituberculous virtues, A. B. Katchkatcheff³ speaks favorably of its sedative and antiseptic effects. The cough is relieved, sleep procured, and the septic processes in the lungs arrested. He employs either thiocol itself in 8 gr. to 10 gr. doses, or sirolin, which is a 10% syrup of thiocol, in tablespoon doses. Thiocol can be combined with quinin, heroin, etc. [L.J.]

OPHTHALMOLOGY

WALTER L. PYLE

EDITORIAL COMMENT

Acute Infections as a Cause of Optic Neuritis.

—In a recent series of studies Antonelli⁴ maintains that practically all the acute infectious diseases may produce optic neuritis, either papillary or retrobulbar. These cases are not so exclusively the result of meningitis or nephritis, as is commonly stated. They may be due to direct actions of toxins on the optic nerve, as in true peripheral neuritis elsewhere. It is well known that they may be associated with intracranial disease and affections of the orbit and adjacent sinuses. Involvement of the optic nerve is generally at first unilateral, but within a week both eyes usually become involved. Unless profound amblyopia lasts more than two weeks, prognosis is good, and the amount of vision recovered is generally in proportion to the duration and degree of visual affection. The prognosis is decidedly bad if the patient has been almost blind for a month. A frequent cause of this form of optic neuritis is influenza, about sixty cases having been reported. Both the papillary and retrobulbar types have been observed, and in almost every instance the cases have been bilateral. Some twenty cases due to malaria have been recorded. Atrophy of the optic nerve frequently follows unless the papillitis occurs during the intense febrile stage. In typhoid fever, affection of the optic nerve generally appears as a subacute papillitis. It is usually a late symptom, but in a few

cases it has appeared early. It is important in these cases to exclude meningitis as the exciting cause. As a rule, complete recovery of vision does not occur on account of a partial secondary atrophy. Although many cases have been reported as occurring in the acute exanthems it is likely that in the majority of these the exciting cause was associate renal or cerebral disease or orbital cellulitis. Syphilis is one of the commonest causes of optic neuritis, and Antonelli distinguishes three distinct types. At least ten cases of optic neuritis following diphtheria have been reported. They resemble in every way the paralyzes of other cranial nerves which so often follow this infection. Serumtherapy has not shown any curative effect, but its value in prophylaxis is undoubted. Beside those cases due to direct extension of infection, there are recorded several cases in which double optic atrophy has followed unilateral facial erysipelas. Optic neuritis is a late complication of mumps and the prognosis in the cases reported has been good. Isolated cases of optic neuritis have been observed in acute rheumatism, typhus fever, pertussis, acute myelitis, and gonorrhea. Hutchinson and Jessop have called attention to the relation of herpes zoster and optic neuritis, and de Wicker states that this association is found in 7% of the cases of herpes zoster ophthalmicus. Antonelli believes that both affections are due to the same toxemia. In all cases of optic neuritis secondary to the acute infections, the treatment should be directed primarily to the causative disease.

Ocular Injuries During Labor.—Even in the course of natural labor, injuries to the eyes of the child are not uncommon. Traumatism of the eye-lids with resultant edema and ecchymosis and conjunctival hemorrhage and chemosis are often seen. According to Thomson and Buchanan there sometimes occur in what may be termed natural, normal, or unassisted labors retinal and choroidal hemorrhages. De Wecker cites a case of face presentation in which an orbit was mistaken for an anus in a breech presentation, and the eyeball gouged out by the obstetrician's finger. In cases of labor necessitating the use of forceps, injuries of the eyeball and adjacent parts frequently occur. Thomson and Buchanan¹ have recently reported the results of their observations in this class of cases in the wards of the Glasgow Maternity Hospital. The chief injuries from the pressure of the blades of the forceps are excoriations, edema, fracture of the orbit, corneal affections, hyphemia, paralysis of the ocular and lid muscles, retinal and retrobulbar hemorrhage, optic atrophy, cataract, dislocation of the lens, exophthalmus and avulsion of the eyeball. They are of the opinion that in cases of contracted pelvis requiring the use of forceps, the extraordinary effects which may follow pressure upon the eyeball lead them to believe that almost any injury to internal structures is possible. They call attention to a peculiar form of traumatic keratitis which, from microscopic examination, they believe to be due to vertical rupture of the posterior elastic corneal lamina. This affection varies in severity from a transient haziness to more or less permanent opacity. Bouchet has observed fracture of the frontal bone, and exophthalmus followed by recovery without paralysis or convulsions. In a case of exophthalmosis and hyphemia following the use of forceps in a primipara, reported by Schroeder, an autopsy revealed hemorrhage into the orbit (which explained the exophthalmus) and detachment of the dura mater from extravasation of blood. Stanheim has observed edema and cicatricial entropion following forceps delivery. In fact, almost every form of ocular injury has been mentioned as proceeding from forceps delivery; yet, the evil results are small in comparison with the enormous number of cases in which this instrument is applied. It is fair to assume that in a vast

⁴ Archives d Ophthalmologie, July-October, 1903.

¹ Transactions of the Ophthalmological Society of Great Britain 1903.

majority of cases if forceps are used with ordinary care and skill, permanent ocular injury is not likely to follow.

The Fallacies in Tenotomy for Heterophoria.—The vogue, now happily waning, of tenotomy of the ocular muscles for heterophoria, was based upon several errors of diagnosis and inference which, although now clearly exposed, have had great influence in the past. Thousands of such tenotomies have been performed worse than needlessly. To review the mistakes and their causes may now be of service in helping the mind to avoid similar blunders of observation and logic: 1. The first mistake was that of taking *post hoc* for *propter hoc*. The advocates of tenotomy looked upon the fault as one of mechanics, the muscles and tendons, their insertions, shape of the orbit, etc., being considered as the only factors at work. We now recognize that these peripheral structures had little or nothing to do with causing the conditions, and that the dominant factor was innervational. The nerve-centers, not the muscles and tendons were at fault. 2. The secondary and tertiary causes were taken for the primary cause. The crude mechanisms of the muscles, tendons, insertions, etc., should have been recognized as the mere instruments of ametropia. 3. The fallacy of "latent" heterophoria vitiated every test and argument. Prisms worn for a time were supposed to make the "latent" defect manifest. In fact they temporarily created a new defect. One can soon create any kind and almost any degree of heterophoria by ordering such prisms to be worn. 4. The advocates of tenotomy found esophoria tremendously prevalent, and called it heterophoria, whereas low-degrees of esophoria are normal, and are desirable for those who use their eyes for much near work. 5. Moderate degrees of hyperphoria are much more certainly, accurately, and easily corrected by prisms incorporated in the lenses required for correction of the ametropia, than by operation. 6. Exophoria is simply insufficient adduction power, and this may be soon and absolutely increased to any extent by prisms, bases out, used as temporary gymnastic exercises. 7. Heterophoria, being a result of ametropia, was not cured by tenotomy, which, indeed, rendered the final cure more difficult, and sometimes even impossible. 8. Crediting the good results which followed tenotomy *plus* proper glasses, to the tenotomy alone, showed incorrectness of observation and an unscientific logic. 9. The disappointment that followed the extended trial and exploitation of the theory involved in the eight preceding considerations has been the greatest source of scepticism and error in recognizing ametropia as the true cause of eyestrain, and of the many systemic reflexes produced by it.

REVIEW OF LITERATURE

The Argyll-Robertson Pupil.—In a recent summary of the literature regarding the clinical significance of pupillary phenomena and the origin of the various reactions, Marburg¹ reviews the various opinions concerning the well-known Argyll-Robertson pupil—loss of action to light stimulus but response to convergence. In regard to its origin he discards the theories of location in the spinal cord and ciliary ganglion and places the center for light reflex in the midbrain in the neighborhood of the nucleus of the iris sphincter. The principal cause of the phenomenon is syphilis and the chief diseases in which it is met are locomotor ataxia, general paralysis, and cerebral syphilis. It may result from injury, or it may be a temporary symptom in numerous diseases, the principal of which are the various neuroses, and the infections, particularly meningitis, influenza, and pneumonia. It may also follow poisoning by atropin, carbon disulfid, lead, the bromids, male fern, poisonous fungi, tobacco, and alcohol. Marburg calls especial attention to the fact that the light reflex is not lost in affections of the posterior column occurring in pernicious anemia. In patients with the Argyll-Robertson pupil in which a

history of syphilis is denied, close inspection will generally reveal aortic degeneration or other sign of preexisting lues. The Argyll-Robertson pupil is often at first unilateral, and in cases in which it is the only symptom present, cure may be affected by immediate antisyphilitic treatment. In case untreated both eyes are likely to be affected ultimately. Persistent reflex immobility indicates a severe cerebral lesion, usually of syphilitic origin. Temporary immobility may be functional, but except in the neuroses, there is usually an associate anatomic lesion, which should be considered in the prognosis. It should also be remembered that syphilis and hysteria may coexist in the same patient. The functional type may often be cured by suggestion and the administration of miotics.

Intracapsular Irrigation in Cataract Operations.—Reik¹ summarizes the results of all the recorded operations of this kind by various operators, cites his personal experiences, and offers the following conclusions: 1. That the introduction within the eye of the sterilized saline solution is harmless. 2. That the removal of cortex is a mechanical process and regulated by ordinary physical laws. 3. That, from the anatomic structure of the eye, and the conditions existing during the operation, irrigation is more efficient in removing cortex than any other method. 4. That just as irrigation removes cortex, so it removes blood and bubbles of air. It also shows the condition of the capsule, gives tone to and replaces the iris and is effectual in making the toilet of the wound. 5. That very free irrigation by the nozles may be practised without fear. 6. That irrigation does not tend to cause prolapse of the vitreous. 7. That the secondary operations form a small percentage.

The Operative Treatment of Trachoma.—J. A. Louria² describes an operation for trachoma, which consists in a thorough extirpation of the infiltrations located beneath the conjunctiva of the upper fold. This procedure has for its purpose the prevention of corneal complications or their removal when once developed. Eighty cases were thus treated with satisfactory results. The indications for operation were: Failure of usual methods, presence of pannus, severe corneal involvement. Certain conditions contraindicate the operation, as fresh corneal ulceration, fresh corneal infiltrations (in such cases we must wait until the acute stage has been passed), and great friability of the conjunctiva of the upper fold. The operation, according to the author himself, is painful and complicated, but is justified by the good results. [L.J.]

Radium Rays and their Influence on Vision.—E. S. London's³ numerous experiments demonstrate that the rays of radium by their action on the retina produce perception of light in the eye even at considerable distance; it matters not from which side the rays come and what substances they have to penetrate. The radium rays, differing from light rays physically, are also dissimilar from them by their physiologic action on the visual apparatus. In themselves they do not augment the visual power of the eye. The radium rays are neither refracted nor reflected by the media of the eyes, but are absorbed to a certain degree by them simultaneously. When acting upon the eye sufficiently long and strong they are capable of producing inflammatory conditions in its various parts (keratitis, retinitis, etc.). Persons with bandaged eyes are able after some practice to recognize the shape of moving radium rays and can name simple figures described with them. Portions of the retina not atrophied can easily perceive this light in the dark room. By the use of this light in various forms and figures, blind individuals, capable of perceiving light can be taught to recognize a large number of optical pictures. This is true of individuals in whom the causes of blindness lie in the nerve apparatus of the retina, or in the transparent media of the eye. London describes a method which he has employed, of teaching a number of apparently blind boys to read, and speaks of it as the "silhouette method." [E.L.]

Cerebral Centers of Divergence and Convergence.—W. M. Bechterew⁴ discusses the facts which render prob-

able the existence of special centers governing ocular convergence and divergence. This illustrious author made a series of experiments on apes in order to obtain reliable data. He found by irritating a certain well-defined area of the cortex in the region of the gyrus angularis the eyes are made to diverge. The same result follows stimulation of an area in the frontal lobe just in front of the middle portion of the precentral fissure. Thus we must assume the existence of 2 cortical centers of divergence. Beside these cortical centers, the author's experiments demonstrate the existence of a subcortical reflex center of divergence located in the 2 anterior corpora quadrigemina, while the 2 posterior corpora contain the analogous subcortical centers of convergence. The cortical centers of convergence are located in the occipital lobe behind the union of the fissura sylvii with the first temporal fissure, and in the lower part of the gyrus angularis, respectively. [L.J.]

Acain-cocain in Local Anesthesia.—W. Krauss¹ recommends the use of acain and cocain as local anesthetic in operations in and about the eye. He employs the following formula:

Acain025 gm. ($\frac{1}{2}$ gr.)
Cocain05 gm. ($\frac{1}{2}$ gr.)
$\frac{1}{2}$ % solution of sodium chlorid5 gm. (75 gr.)

The solution should be fresh for every operation. If much hemorrhage is expected a few drops of a 1 to 1,000 adrenalin solution may be added. He has employed it for enucleations, strabismus, chalazia, lid operations, etc. [E.L.]

The Diagnosis of Orbital Tumors.—F. Terrier and V. Morax² speak of the differential diagnosis of orbital tumors. After briefly mentioning inflammatory lesions, syphilis, osseous tuberculosis, actinomycosis, and vascular tumors, the diagnosis of which should not present great difficulties, 4 other classes of tumors are considered: 1. Tumors of the optic nerve. 2. Osseous tumors of the type of true sarcomas. 3. Tumors originating in the sinuses or nasal passage and extending to the orbit secondarily. 4. A group of tumors apparently originating in the periosteum or fibrous tissue of the orbit and variously described under the names of fibroma, fibrosarcoma, or fibromyxoma of the orbit. The latter type is considered at length, 2 cases being reported and a table containing 14 other similar cases appended. Both patients were males, one being 62, the other 36. The tumor in each instance was removed and there has been no recurrence, one after 4 months, the other 9 months. The slow growth of these tumors, the absence of recurrence (several of the reported cases showing none after 7 years), and the histology, place them among the benign growths. The structure is that of connective tissue containing many fusiform or polyhedral cells and in many instances the bloodvessels are numerous. The vessel walls are distinct, with muscular and fibrous layers, a point separating the tumors from true sarcomas with their thin-walled vessels or mere blood channels. [A.G.E.]

Latticed Corneal Opacities.—H. Freund³ describes 15 cases of this rare disease occurring in two families; it varied in intensity in each case depending upon the length of time it existed. He finds that the disease always begins after puberty and affects both eyes, but usually one eye more than the other. Among his cases the right eye was usually more diseased than the left. During the first stage there are no subjective symptoms. The first symptom is usually an irregular refraction of light due to the formation of nodules, which may be seen about the center of the cornea; they are made up of numerous fine lines arranged irregularly. Gradually vision diminishes as the corneal cloud and the nodule formation increases. The individual lines can only be recognized toward the periphery of the process. Usually an active keratitis arises toward the latter years of the affection and the corneal epithelium degenerates. The peripheral part of the cornea never becomes affected by the disease, therefore an iridectomy in the latter stages often improves vision considerably. The disease occurs in families and is hereditary. [E.L.]

Gummatous Tumors of the Sclera.—These growths are

an extreme rarity, and most textbooks ignore them entirely. According to A. W. Lotin¹ there are only 16 reported cases in literature. He adds an original observation of his own. A man of 43 presented himself with symptoms of an intraocular tumor. The eyeball was enucleated and a white growth found to surround the eye in the equatorial direction. Microscopic examination revealed the features of gumma. The diagnosis of gummatous growths of the sclera is naturally quite difficult. If recognized early, specific treatment offers an excellent outlook, the tumor often disappearing entirely. In later stages, however, but little can be expected from antisyphilitic remedies. The consequences of advanced gumma are very disastrous, often ending in total blindness, as in the author's case. [L.J.]

Aspirin in Ophthalmologic Practice.—O. Neustadter² has employed aspirin for its sudorific, antirheumatic, analgesic, and antipyretic action. It is superior to the salicylates in the two latter indications. He advises it in iritis, optic neuritis, scleritis, etc., in large doses, giving as much as 7 gm. (75 gr.) in the 24 hours. He has never seen ill results from it, but says it must never be given in simple aqueous solution, as the ordinary gastric juice cannot dissolve it. An acidulated solution is necessary, and he gives it preferably with hot lemonade. [E.L.]

Congenital Glaucoma.—E. Stevenson³ reports a case in a boy of 5. The eyes were larger than normal in every diameter, the anterior chamber very deep, the irides somewhat tremulous owing to the stretching of the zonule of Zinn, the lens clear. The tension was slightly increased, the optic nerves cupped. In the development of the eyes before the iris and ciliary body receive any definite formation the lens is pushed off from the posterior surface of the cornea by a mesoblastic structure called the anterior fibrovascular sheath, which eventually in its anterior portion goes to form part of the cornea, and in its posterior portion the pupillary membrane. At this time there is no anterior chamber. The latter forms by separation of the sheath from the cornea and the iris pushes its way in between the structures, incorporating with itself portions of the sheath, which strip themselves from the cornea and lens. If there is any failure on the part of the sheath to strip off from the periphery of the cornea it and the iris would effectually block the filtration angle. Owing to the site of the obstruction the aqueous begins to collect in the anterior chamber and distend it. Iridectomy generally results in dislocation of the lens. The tension may be kept down by miotics, but nothing stops the increasing nerve atrophy. In one or two cases stretching has opened the angle with partial recovery. [H.M.]

Treatment of Trachoma with Knapp's Roller Forceps.—I. Hoppe⁴ gives Knapp's roller forceps the preference over all other treatments for trachoma, because of its rapid results, easy technic, and absence of danger. Neither assistant nor ether is necessary, and the patient can come to the physician's office. The instrument is to be used only in case follicles are to be expressed. It may be necessary to repeat this, and, in fact, should be repeated so long as new follicles develop. [E.L.]

Retinal Hemorrhages in Severe Anemia Due to Bothriocephalus.—A. S. Tchermolossoff⁵ finds such hemorrhages to be a constant phenomenon in the severe forms of anemia produced by *Bothriocephalus latus*. The form of hemorrhages is round, striped, or semicircular. They are usually located near the vessels about the posterior pole. Their course has an important influence on the prognosis. The bleeding takes place by diapedesis, the blood is reabsorbed entirely, and inflammatory phenomena are absent. The keenness of vision, and the other ocular functions are unaffected. These hemorrhages, occurring in the anemia of bothriocephalus, are identical with those of essential pernicious anemia, and offer an additional argument in favor of the identity of both anemias. The diagnosis of tapeworm anemia is facilitated by the general appearance, the absence of skin complications, and the lack of inflammatory symptoms on the retina. [L.J.]

Contract Medical Practice.—Disapproval of the conduct of physicians who contract to furnish medical attention at less than minimum prices to members of clubs, societies or orders has been signified in no uncertain manner by the Stearns-Benton (Minn.) County Medical Society. Resolutions recently adopted by the society set forth that certain members have accepted such positions to the detriment of the practice of medicine and to the dignity of the profession; that the society has resolved to strike from its rolls the names of such members after due notice has been given them; and that the members of the society, individually and collectively, shall not consult with or call in consultation any physician who practises in such manner. This at first sight appears a rather summary and drastic procedure on the part of the society, but it was taken with a full knowledge of the local conditions and doubtless after a thorough discussion of ways and means for meeting them. Such action will relegate the rejected physicians, so far as professional recognition is concerned, to the rank and file of those who practise the quack "pathies" of various unctuous designations. Perhaps certain of them will have found their true place; others do not deserve such a fate. We congratulate the physicians of Stearns and Benton counties on possessing the courage of their convictions in thus dealing with a question that needs settling in many other localities. When well-to-do persons join societies for the sole purpose of reducing their expenses for medical attendance, there is somewhere a violation of the spirit, if not the law, of the code of ethics.

The Meaning of Certain Medical Terms.—The March and April numbers of the *American Journal of Pharmacy* contain a symposium on the meaning of the terms pharmacology, pharmacognosy, materia medica, and certain related words. This symposium is made up of the replies of physicians, many of them teachers in the above branches, to letters from the editor of the journal asking their interpretation of the aforesaid terms. The very laudable purpose in view was to have these terms defined according to their modern acceptation and uses, and thus clear the existing confusion in regard to their meaning and employment. A dozen answers have been received from such authorities as Wood, Hare, Sollmann, Potter, Shoemaker, Hallberg, Abel, and others. A few

discuss at some length the etymology of the words, but the majority of the writers furnish simply their personal preference and usage. To epitomize the views expressed is a difficult task; they must be read in full to be properly appreciated. Broadly speaking, there is a tendency to regard pharmacology and pharmacognosy as partially synonymous terms, either of which, in its wider sense, may be used as a substitute for the older one of *materia medica*; pharmacology has decidedly the preference, several of the writers looking upon pharmacognosy as superfluous. In the restricted sense, pharmacology represents the experimental, and pharmacognosy the descriptive side of *materia medica*. This commendable symposium should result in a better understanding of the terms under discussion; we wish that it might accomplish more, namely, a common usage. As stated by one of the writers, however, it is probable that nothing less than the *fiat* of an academy would suffice to bring order out of the present chaos.

The Achievements with the Ultra Microscope.—In our issue of August 22, 1903, we briefly referred to the interesting discovery, made by Siedentopf and Zsigmondi, of a microscope with wonderful resolving power. The principle involved is an intense illumination of the particles to be examined, while the background remains absolutely dark. The resulting image is analogous to that seen when the telescope is directed toward the Milky way. In the ordinary microscope, the conditions are reversed, the field being illuminated and the objects to be examined remaining dark or possessing whatever color may be given to them by staining. Particles with a linear diameter of .000001 mm. have been rendered visible by means of the new microscope. The original instrument has been somewhat simplified by two Frenchmen, Cotton and Mouton, and now conforms more nearly to the ordinary microscope. One of the first discoveries of practical value to be made with the instrument is that of Raehlmann,¹ who found, in the aqueous and vitreous humors of an eye enucleated on account of sympathetic ophthalmia, what appeared to be actively motile bacteria, chiefly rod-shaped. None were seen in the nerve-disk. The magnification employed in these studies was 2,400 diameters. Raehlmann expresses the belief that sympathetic ophthalmia is

¹ Deut. med. Woch., March 24, 1904.

a metastatic infection with microorganisms. The length of time intervening between the injury to the first eye and the appearance of symptoms in the second, usually not less than six weeks, is, he thinks, closely related to the growth of the bacteria and to the time when spore formation is reached. The reason that the infection, although carried to the other eye by the blood, is not demonstrable elsewhere, is that these bacteria will thrive only in the vitreous humor, which constitutes a medium peculiarly suited to them, and one that is found nowhere else in the body.

To Destroy Heroism.—From a reading of the conditions of Mr. Carnegie's endowment fund to encourage heroism by means of helping the dependents of heroes or themselves in case they are only injured in the effort to save the life of their fellows, it is intended that physicians and nurses should be specially rewarded. It may well be feared that the plan will defeat its own object in any case, but we doubt if the medical or nursing professions will welcome the proposal. In the first place, the fund should be a hundred instead of five millions, because every good physician and nurse would have to be included; they almost daily risk their lives for their patients' sake. It is really habitual with them—a part of their duty and function. Moreover, the plan of public rewards, and especially of money-giving, emphasizes the melodramatic kinds of heroism of the cheap novel and stageland varieties, at the expense of the more effective, useful, and needed types—which are secret, modest, and persistent in their actions and motives. Then there is the great danger, almost certainty, of stimulating the sham heroisms that boast of their own exploits, or that are brought to light by the hero's friends. The purest virtue and the most genuine heroic quality not only do not ask for reward or praise, but shrink from it with spontaneous shame. The "Hero Fund" appears to be a device for discouraging the fundamental conditions which produce heroism and of replacing it by the spurious varieties altogether too prevalent already.

The sentence, death, burial, and requiescat of eyestrain were all carried out in one evening at a recent meeting of some members of the New York Academy of Medicine. There was a commendable expedition in the proceedings consonant with the worthiness, or unworthiness, of the cause; a hearty unanimity of the judges and jury; the chorus was in excellent voice; the ceremonies were solemn, although strangely amusing, both to the officiating persons and to the spectators. There was but one that had a good word for the dead dog, a noteworthy exception to the old rule *nil nisi bonum*. Dr. Dana had not been able to find in 20 years any case, even of any minor psychosis, due to eyestrain—at least, "hardly any." "Success was generally attained without treating the eyes."¹ "Glassing had become a real psychosis, etc." Dr. Cutler said that if sick headache was cured by the correction of astigmatism

the fault was not with the eyes but with the unstable nervous organism which migraine finally resolved itself into. Dr. Sachs said that those who contended that epilepsy, chorea, and other motor disturbances of the nervous system were due to eyestrain had "axes to grind." Dr. Holden spoke of anesthesia, hyperesthesia, contraction of the visual fields, color perception, etc. Dr. deSchweinitz was glad of the firm stand taken on the conservative side. Dr. Collins said no case of migraine had been cured, remedied, or benefited by glasses. Dr. Knapp said eyestrain was due to overexertion of the eye. But hundreds of articles have been written and thousands of cases reported by reputable physicians absolutely contradicting the assertions of these gentlemen—"all honorable men"—and there are thousands of physicians who are convinced that their assertions are errors. And why the great special meeting of the Academy to lay such a poor, squeaking and gibbering ghost?

"The Nervous Woman, and What to Do With Her," is the title of an article in a recent number of a medical journal. "The Lord deliver me from her," is the text, and a devout sermon is preached. The subject is apropos, for the nervous woman occupies more and more of the attention of the medical profession, and the intolerable torment of her is already an old story. Such women occupy almost the exclusive attention of very many specialists. And yet the author of the article says: "There has been less time given to her by the leaders of medicine than to any other subject that is so important and pertinent to both patient and physician." There is no literature about her, he says, and no help as to treatment is to be gained from the literature. This seems somewhat severe on the rest-cure and "forced sleep" treatments so glaringly in vogue everywhere. For whom, pray, are these private sanatoriums, forced feedings, forced sleeps, and three-months-in-bed, if not for the "nervous women"? Several illustrative cases are described of these most bothersome patients, and there is the greatest fun derived from the details. When the author got the first "apocalyptic creature puking," he did "the smartest thing in his life." The second patient was an anemic woman, who from girlhood had had attacks of "severe cephalgia," so severe that her sight had been affected after an attack. After three or four years "excruciating [pains]" began "from the occiput down to the dorsal vertebrae," with mild paresis of the lower extremities. From hospital to hospital she was taken, and all sorts of treatment tried for her spinal irritation. Finally, after everything else had been tried, "Flint's Tablets" seemed to "control the cephalgia better than anything that had been tried." But it is added that "nothing will cure these patients quickly, or in every case permanently."

"Case III and Case IV" of the series noted above are noteworthy. When first seen there was in Case III pain in the head, with facial erysipelas, great neuralgia in the abdomen, and soon uncontrollable vomiting. This persisted until extreme weakness followed, and rectal feeding was necessary. The medical treatment

¹"It is these patients [neurasthenics] who sometimes have long-standing and inscurable headaches and local pains. They 'never remember being without a headache' or pain in the back. No form of treatment has ever helped this."—[Dr. Charles L. Dana, in the *Boston Medical and Surgical Journal*, March 31, 1904.]

was a "total failure," although every drug that "by any ingenuity could be thought of any value" was tried. Tonic spasm of the arms followed, and "hysterical aphonia." Chloroform was used; the spasms relaxed, "only to return." Splints were required "to keep the arms and legs extended." The mental condition was perfectly normal, and there were absolutely no hysterical manifestations. Plain starvation was ordered for the vomiting. A long disquisition on the drug treatment follows. Of Case IV, the woman worked hard in her business from 2 o'clock a.m. until 4 p.m. "Migrating neuralgias," poor appetite, insomnia, etc., followed. No organic trouble whatever was to be found, although, "as in all such cases," there was "obstinate constipation." "The voyage to recovery was very tedious," "all sorts of drugs were tried," and a removal to a sanatorium was planned, when *avena sativa* brought about apparent recovery. "The therapeutic nihilist will be a therapeutic failure," it is said, and the advice is given to try one drug after another "until somewhere and somehow" will be found the patent remedy. There is one capital recommendation—the dependence of these diseases upon affections of the sexual organs is disallowed. But the writer seems to have made several slight errors. He appears unaware that innumerable cases of the kind, with the facial erysipelas, paresis, and the rest, have been described; that by the older writers they were called cases of migraine; that in nine out of ten such cases the migraine or "nervousness" is due to eyestrain.

The Medical Secret and Marriage.—The tendency of modern medicine is toward the prevention of disease, and the individual physician as well as the medical profession in general should be instrumental in accomplishing this end. While the scope of the physician's activity in disseminating the knowledge he has gleaned through study and experience is practically unlimited, he is, by virtue of his oath to secrecy, prohibited from disclosing, even for the most laudable purposes, any information derived from an individual case. The physician may give advice to his patient, warn him of the inevitable outcome of his marital union, depict in glowing colors the subsequent physical and spiritual misery of his spouse, but here he must rest and leave it to the patient's unselfishness and sense of honor to follow his counsel. Truly, Wordsworth's definition of honor applies forcibly to such instances:

"Say, what is honor? 'Tis the finest sense
Of justice which the human mind can frame,
Intent each lurking frailty to disclaim,
And guard the way of life from all offence
Suffered or done."

The Interest of the Community Versus that of the Individual.—Since the strength of the State depends upon the health of the citizens, the law has decreed that all infectious diseases should be reported to the proper authorities. Venereal diseases are most certainly "infectious," but as regards them there is practically no legislation in any State of this country. Among European nations, however, laws intended to check their dissemination are enforced. In France, the

physician is compelled to warn the nurse of an infant afflicted with congenital syphilis of the dire consequences which may await her, and if he fails to do so he can be held responsible for untoward results. In Norway and Sweden the declaration of venereal diseases is made obligatory, and, although the information is kept secret by the sanitary commissions, it has proved a potent measure of prophylaxis. However, the interest of the individual is often at variance with that of the community and causes the patient to shirk the disagreeable ordeal of confessing his malady. Syphilis and other venereal diseases are considered, with more or less propriety, "shameful" affections, and place the thus afflicted in a most humiliating and reprehensible position. Public cognizance of this fact will undoubtedly make him a social pariah. Members of the most exclusive society, women and men enjoying the admiration and respect of the public, as well as those of the lowliest station would be alike affected by laws instituted for the purpose of curtailing the reach of this dreadful scourge. Every practitioner knows what manifold interests are often at stake when syphilitics contemplate marriage and apply to him for advice. Here the pity for the young woman should deter the man from entering wedlock, and yet, a host of obligations and ulterior motives from the material standpoint and also from the viewpoint of society would seem to make the alliance obligatory. Only too often the candidates for marriage are swayed from the straight and honorable course by the thought of "what will the world say?" and such consideration may outweigh all others. The doctor finding his benignant efforts entirely ignored and being bound by professional secrecy must feel like an accomplice when he beholds the havoc he might have averted. Small wonder that he entertains doubts occasionally as to the wisdom of the Father of medicine. Here Goethe's immortal words are again verified: "Es erben sich Gesetz und Rechte wie eine ew'ge Krankheit fort." Is it not incongruous in the face of present needs to bind oneself by an oath, based, it is true, upon ethical conceptions, yet one the originator of which in all likelihood would never have made unconditional, had he been aware of the dilemma in which it places the modern medical profession?

The "Drug-store" Competition with the Doctor while "Soliciting His Patronage."—In a recent issue of a "reputable" newspaper in an eastern city there are 91 advertisements of 91 druggists of the city, each lauding the secret and proprietary preparation manufactured by the druggist as cure-alls for all the diseases which professional men are called upon to treat. A few of these 91 infallible remedies are as follows: For any case of kidney disease, Dyspepsia, All diseases of the blood, Sore throat, Bronchitis, Any case of cough, Cholera, Asthma, Any troubles from disordered system, All headaches and neuralgias, Influenza, Rheumatism, Whoopingcough, Tapeworm, Croup, All lung affections, Malaria, Tuberculosis, All diseases of the nervous system, etc. In every village and city of the United States the same principles of business are being pushed. In the same newspapers, and even in the same advertise-

ment, the druggist asks for the physician's patronage, and guarantees that "prescriptions will be compounded with care." It would seem as if there is a strange confusion of mind on the part either of the enterprising nostrum maker, dealer, and advertiser, or of the patronizing physician. Does the physician really patronize? Should not the local medical societies warn their members, and blacklist the druggists who dishonor two professions and humbug the public at one business stroke?

The Sale of Narcotics, Poisons, etc., by the Country Store Grocers.—Dr. Charles E. Abbott of Buffalo sends us the following letter. The matter seems of such importance that special attention should be called to it. It has of course far more than a local significance:

I enclose herewith a copy of the act amending the Public Health Law recently introduced in the New York State Legislature. Superficially this amendment would seem entirely harmless, yet upon close scrutiny will be found lurking within its substance that which is not only harmful but an absolute menace to the welfare of the community in general. Those responsible for the introduction of this measure are a few petty drug jobbing houses whose principal income is obtained by selling what are called U. S. P. laudanum, paregoric, tincture of iodine, gum opium, morphin and various other drugs to the general merchants doing business in rural communities; and whose income from this source has been largely curtailed through the operation of the present Public Health Law, and By-laws of the State Board of Pharmacy which prohibit absolutely the sale of opium, morphin, chloral and cocain, and limit the sale of such articles as laudanum, paregoric, tinctures of iodine, arnica, spirit of niter and quinine to one person in any community three miles or more from the nearest regularly licensed drug store; provided, however, that the necessity for the sale of such articles is shown to exist, and the person offering such articles for sale is, in the judgment of the State Board of Pharmacy, qualified to do so. He must also keep a record of all sales of laudanum in a book provided for that purpose, giving the name of purchaser, date and purpose for which it is to be used. In event of the proposed amendment becoming a law, any person, be he grocer, milk dealer, confectioner or blacksmith, no matter whether he is located next door to a regularly licensed pharmacy or drug store or 50 miles distant he may sell any or all of the 997 official drugs and preparations of the United States Pharmacopeia, or in fact anything, provided the package bears the label of a licensed pharmacist. (How easy to procure this!) Prior to the enactment of the present law, over which these petty drug jobbing houses have become so disgruntled, a most alarming condition of affairs existed regarding the sale of poisonous drugs. I shall mention a few instances that are known to me as positive facts. A grocery dealer in a certain village kept in his store room a sugar barrel filled with empty one-eighth ounce morphin bottles; when asked how he came to have such a number he stated that they represented the morphin he had sold; his customers had returned the empty bottles because he allowed one cent each for them. In another instance a grocer sold a two ounce bottle of laudanum which was taken from a large stock container. Having no laudanum label he placed a paregoric label upon the package, drew a pencil mark through the word "paregoric" and filled in the word "laudanum" in pencil, leaving printed directions for paregoric dosage, in this case the adult was from one to four teaspoonfuls. In still another instance a small boy employed by a general store keeper doing business in a rural community sold an ounce of gum opium without question to a person known to me. He weighed it upon a bare scale pan and delivered it in a plain paper bag. Another instance which happened in a village with a population of 500 containing a well-appointed pharmacy conducted by a man who is a graduate

in pharmacy and a Doctor of Medicine, a person known to me, bought laudanum without question in a candy shop, grocery store, and blacksmith shop. Is it any wonder the drug habit is on the increase under such conditions!

Another absurdity of this amendment is that it says nothing of the registration of poison sales. The present Public Health Law under section No. 198 of Chapter 667 requires the registration of arsenic, potassium cyanide, hydrocyanic acid, cocain, morphin and strychnin, and other poisonous vegetable alkaloids and their salts, oil of bitter almond containing hydrocyanic acid, opium and its preparations, except paregoric, and such others as contained less than two grains to the ounce. A strong effort was made to pass this amendment last year, but fortunately owing to the unflagging energy and zeal put forth in the effort against it by Mr. Warren L. Bradt of Albany, Secretary of the State Board of Pharmacy, it was blocked in the Senate. Great credit was also due to Dr. Willis G. Gregory of Buffalo, Dr. Muir of Brooklyn, Mr. Judson B. Todd of Ithaca, Mr. Bryon M. Hyde of Rochester, and Mr. Charles B. Sears of Auburn who rendered Mr. Bradt able assistance. It is to be hoped these same gentlemen may be able to defeat this measure again. I believe it the duty of every physician in the State to unite in protesting against it.

The wording of the act is as follows:

SECTION 1. Section one hundred and ninety-nine of chapter six hundred and sixty-one of the laws of eighteen hundred and ninety-three entitled "An act in relation to the public health, constituting chapter twenty-five of the general laws," as added by chapter six hundred and sixty-seven of the laws of nineteen hundred, as amended by chapter six hundred and forty-eight of the laws of nineteen hundred and one is hereby amended to read as follows:

§ 199. Application of article limited.—This article shall not apply to the practice of a practitioner of medicine who is not the proprietor of a store for the dispensing or retailing of drugs, medicines and poisons, or who is not in the employ of such a proprietor, and shall not prevent practitioners of medicine from supplying their patients with such articles as they may deem proper, and except as to the labeling of poisons it shall not apply to the sale of medicines or poisons at wholesale when not for the use or consumption of the purchaser, or to the sale of paris green, white hellebore and other poisons for destroying insects, or any substance for use in the arts, or to the manufacture and sale of proprietary medicines, or to the sale by merchants of domestic remedies when sold in the original packages bearing thereon the label of a licensed pharmacist, of ammonia, bicarbonate of soda, borax, camphor, castor oil, cream of tartar, dye stuffs, essence of ginger, essence of peppermint, essence of wintergreen, nonpoisonous flavoring essence or extracts, glycerine, licorice, olive oil, sal ammoniac, saltpetre, sal soda, epsom salts, rochelle salts, and sulphur, except as herein provided. Provided, however, that in the several places in this state, outside of incorporated cities and villages, and in incorporated villages of the fourth class, said places and villages not having therein a regularly licensed pharmacy or drug store, physicians may compound medicines, fill prescriptions, and sell poisons, duly labeling the same as required by this act, and merchants and retail dealers may sell the ordinary [nonpoisonous] domestic remedies, provided, however, that all poisonous domestic remedies so sold shall be sold in the original packages bearing thereon the label of a licensed pharmacist.

EXPLANATION—Matter underscored ————— is new.

London Housing Problem.—According to a recent census compiled in London it is observed that over 36 000 single rooms are occupied by three or more persons, and the deathrate among this section of the population is nearly double that for the rest of the community. As an example of the perils confronting us, the correspondent cites the case of Finsbury, where the population of one-room tenements totals 14,516. The deathrate per 1,000 in 1903, was 38.9, yet the rate among occupants of four or more rooms was only 5.6, and for the whole borough 19.6. Of these rather more than one-half were deaths from infectious and respiratory diseases, while deaths from these causes among the "four-roomers" were only 6.7. The authorities state that "something will have to be done soon, but it is one of the most difficult problems to solve. They cannot abolish the one-room system; that is obviously impossible, and were it not so, it would be a gigantic task to provide for this wretchedly poor class of tenants." "To suggest regular inspection seems tampering with the 'poor man's castle,' and yet that appears to me to be the only practical solution. There should also be a limit to the number of occupants, not more than two persons being allowed to live in a one-room tenement."—[*London St. James' Gazette*.]

AMERICAN NEWS AND NOTES

GENERAL.

Bequests to Charity.—By the will of the late Mrs. Henry Farnham, of New Haven, Conn., Yale Medical School receives a legacy of \$54,500.

Miscellaneous.—On April 7, the bacteriologic department of the Stearns Laboratories, at Detroit, Mich., celebrated the wooden anniversary, the laboratory having been founded April 7, 1899. A number of physicians participated in the celebration, being the invited guests of the firm.

Even They Die!—Carol Norton, a wellknown eddyite, propagandist, lecturer, and formerly a "first reader" in that sect, died recently in Chicago. Death occurred at the untimely age of 34. He was a favorite pupil of Mrs. Eddy, and had conducted an institute for training "faith healers."

The Anglo-American Medical Association of Vienna was organized February 6, 1904, with 56 members and it now has a membership of 80. The object of the Association is to promote social fellowship among the English-speaking physicians studying in Vienna, to advance the scientific interest of its members and to aid in quickly orienting the newcomer in the medical and scientific courses given in Vienna. Professors Ortner, Finger, and others, have thus far addressed the Association. The president of the Association is Dr. A. N. Ravold, of St. Louis; the executive committee is composed of Drs. J. H. McHenry, Cleveland; F. W. Van Kirk, Zanesville, Wis.; and J. L. Jacques, Chicago.

Does Walking Prevent Appendicitis.—A New Jersey physician brings forth the idea that one reason for the increased prevalence of appendicitis is decrease in the habit of walking. Says he, "the trolley car has made us lazy, we now ride where we should walk, and I think that appendicitis is due almost wholly to that fact." He asserts that appendicitis in rural districts is comparatively rare, while the cities and suburban towns are scourged with it; that the constant motion of the body, the contraction and relaxation of the abdominal muscles, the increased peristalsis, etc., induced by the ambulatory effort altogether materially assist in reducing the tendency to inflammation of the vestigial remnant. Moral: Get rid of the germ of laziness and walk.

The Many-sided Doctor of Ancient Times.—An exchange says: Sir Arthur Conan Doyle practised medicine before he began to write, and in one of his scrap books he has a newspaper advertisement that he cherishes because it shows well the low standing of many doctors in the eighteenth century. Sir Arthur clipped the advertisement from a newspaper of the year 1787. It reads: "Wanted, for a family not blessed with good health, a sober, discreet and steady person to act in the capacity of doctor and apothecary. He must often act also as a steward and butler, and occasionally dress hair and wigs. He will be required to read prayers and sometimes, on wet Sundays, to preach a sermon or two. A good salary will be paid and a preference will be given to such an one as, beside the above qualifications, can mend clothes."

Drugs Vilely Adulterated.—A United States Senator from Idaho recently made an address in the U. S. Senate on the pure food question, advocating the McCumber Bill instead of the Hepburn Bill. He is quoted as saying, "The physicians of the country want the legislation because under existing conditions they cannot have their prescriptions filled as they wish. Out of 14 samples of drugs advertised, 13 were found to be rank frauds. More than 50% of the patent medicines are deleterious to health, while a large percent are absolutely poisonous. There is a determined opposition to the bill on the part of newspapers which advertise the nostrums." The speaker stated that he had been approached by men representing influential papers asking him to strike out the provision relating to patent medicines; one had stated that it would injure his business to the extent of \$40,000 a year.

A Fruitful Cause of Pneumonia.—A New York physician asserted, at a meeting of a medical society recently, that steam heat is the underlying cause of the pneumonia epidemic which has scourged the metropolis this winter. Steam heat is superheat of excessive dryness. It is heat unaccompanied with a renewal of the air in the apartment heated. It produces an irritation of the respiratory tract, induces perspiration and otherwise places the individual in an absolutely receptive condition for the lodgment of pneumonia germs. It is to be noted that pneumonia claims few victims among women. Most women pass the day in houses heated by furnaces, or, if they do live in steam-heated flats, they are not "in and out" like business men, encountering severe changes of temperature a dozen times a day. The average steam-heated room is merely a superheated box in which the occupants breathe the same air over and over again. So long as this is true the indictment of steam heat as a pneumonia breeder will continue in force and effect.

Child-saving Laws Sustained.—According to *Charities*, the recently enacted child-labor law in New York City has been sustained by a decision rendered by Judge Roesch. The case in action was brought by the city of New York against the Chelsea Jute Mills, a Brooklyn corporation employing many women and children, to recover a penalty of \$50 for violation of the compulsory education law. This law, which was substantially amended as a part of the child labor committee's work of last year, provides that an employer who employs a child under 14 years of age, during any part of the term in which schools of the district in which the child resides are in session, shall be subject to a penalty of \$50, recoverable by the city. The Chelsea Jute Mills employed an Italian girl of 11 years, who had produced an affidavit from her father stating that she was 16 years of age. The city brought suit against the firm and the latter's defense was that the firm acted in good faith, having relied upon the affidavit of the parent that the child was 16, therefore they could not be punished for employing her. Judge Roesch overrules this contention, holding that an employer who employs a child under 14 years of age does so at his peril and cannot successfully plead that he does not know the child to be under the legal age.

Infant Mortality in the Philippines.—The Board of Health for the Philippine Islands reports for November last the deaths of 404 children under one year of age, from causes variously reported as convulsions, eclampsia, and tetanus, and adds: Of these, 153 occurred within 30 days after birth. The more prominent symptoms presented by these three causes largely resemble each other, and it is believed that the latter are often confounded with each other, particularly since deaths of this class largely occur in the absence of medical attendance and the death certificates in such cases must be made out on the basis of the symptoms given by members of the family. There is strong reason for the belief that the deaths occurring in the first month after birth and attended by convulsions chiefly depend upon tetanus infection at the umbilicus, due to the handling of the unhealed stump of the cord with unclean fingers and the common local practice of massaging the abdomen of the newborn. For their prevention the Board of Health has prepared a popular circular on the treatment of the new born and the care and feeding of infants, and has also authorized for the future gratuitous issue of a yard of flannel to each infant whose parents are financially unable to procure suitable clothing for its proper protection against exposure during the first few months of life.—[*Chicago Chronicle*.]

EASTERN STATES.

Spotted Fever in Hartford, Conn.—Information April 13 says: An epidemic of spotted fever, or spinal meningitis, is reported in Hartford, and the Board of Health has quarantined all houses where the disease is prevalent and ordered the strictest regulations of contagious and infectious diseases observed, although spotted fever has never been on either list. Seventeen cases of the disease were reported last week, as against one or two cases a month, the former record. Eleven deaths have occurred. Physicians admit that they are practically powerless to fight the epidemic, as very little is known of the cause and of the malady. This is the most serious epidemic that has ever visited Hartford since the spotted fever plague, which swept through there in 1874.

NEW YORK.

Objection to Increased Tuition.—It is stated that objections to an increase in tuition fees from \$200 to \$250 is making itself felt at the College of Physicians and Surgeons, especially among the students of the first, second, and third classes. The resistance to the increase has culminated in the submission to the university authorities of a petition, signed by the medical students, protesting against the increase, and setting forth their reasons.

New York's Loss by Preventable Disease.—A New York exchange says: Millions upon millions of dollars annually lost to the people of the State of New York through preventable diseases, is the keynote of the annual report of State Health Commissioner Lewis to the Governor. "If the monetary value of a human life is assumed to be \$5,000," says Dr. Lewis, "the deaths from but five of the preventable diseases during 1903 in this State represent a loss of \$94,960,000. These figures seem appalling, and yet millions upon millions can properly be added to this sum, in loss of wages, expense of the care of the sick, and many other expenses incidental to the management of these epidemic and infectious diseases."

Longevity of New Yorkers.—An exchange says: The actual figures show that old people in New York constitute each year a larger proportion of the total population. In the city last year, of 65,000 deaths, 9,354 were those of persons of more than 65—a remarkably large percentage and a higher percentage than was recorded in the vital statistics of any other city in the world. The year before, 1902, out of 66,000 deaths, only 8,880 were of persons over the age of 65, and each year the number of those who pass the 65 year limit is not only a larger proportion of the total number, but a larger number of deaths in New York being now less each year than in the year preceding, though the whole population is, of course, increasing. It is a

somewhat curious fact that the extremes of age are reflected in the seasons. Thus the largest mortality of those over the age of 65 is in the three months of December, January, and February, when the infant mortality is least, and the number of deaths among children is largest in the three months of June, July, and August, when the number of deaths of those over the age of 65 is smallest.

PHILADELPHIA, PENNSYLVANIA, ETC.

The New Jersey Training School for Feeble-minded Boys and Girls, in its fifteenth annual report, contains a detailed report of the work which has been accomplished in training feeble-minded children, the expenses incident thereto, and their hopes for the future. The sentiment of the school is expressed in a few general remarks at the end of the report, which are as follows: The keynote to our training is encouragement. There is no corporal punishment in this institution. Discipline is simple because everything is a special privilege, and therefore a pleasure to do. Within our means no expense or pains are spared to secure the comfort and welfare of our children. Our school belongs neither to the State nor to a private individual, but is a public benevolent institution controlled by an association of philanthropic people. We aim to secure the chief advantages of both State and private institutions, with the fewest possible disadvantages of either.

The Proposed Diphtheria Hospital.—Plans for the diphtheria building at the new Municipal Hospital have been approved by Director Martin. In a short time this hospital will be begun, and contracts will also be let for the other buildings. Each building will be equipped with special disinfecting rooms, and no one will be permitted to leave until he or she has taken an antiseptic bath and has made a change to sterilized, clean clothing. The diphtheria hospital building, which is the type for the two other main buildings of the hospital, will be a semicircular two-story structure, with the outer wall as the circumference of a circle 800 feet in diameter. Inside this building will be merely an eight-foot wide corridor, and at intervals there will be entrances to two-story ward buildings, built inside the circle, and 50 feet apart. Midway between the total of eight hospital buildings proper, which will accommodate 40 patients each, there will be the doctors' quarters, kitchens, laundry, etc.

SOUTHERN STATES.

Sanitary Barber Shops in Maryland.—The hygienic bill providing for certain sanitary rules to be applied to barber shops in Maryland has passed both houses of the Legislature. It is a bill entitled an act to regulate the practice of barbering in the State of Maryland, to establish a State board of barber examiners, to provide for the sanitary inspection of barber shops and to provide penalties for violation thereof. The bill appears to be modeled after the New York law pertaining to this same subject and makes specific requirements concerning the sanitary measures to be observed in all barber shops; providing also that barbers shall be licensed by a State board of examiners.

WESTERN STATES.

Chicago Board of Education.—The Chicago Board of Education has voted to establish medical inspection in all schools. Teachers are to report diseases and unsanitary conditions where the general health is menaced.

A Memorial Hospital to be Built.—It is stated that Harold F. McCormick has acquired, by purchase, a suitable tract in the city of Chicago, and will erect a new hospital to be known as the Memorial Hospital; \$500,000 will be expended on the construction of buildings in the near future.

Lectures on Problems of Scientific Medicine.—The Medical department of Western Reserve University, Cleveland, contemplates a series of advanced lectures on current problems of medical science. The object will be to take up a circumscribed topic, "Treating rather exhaustively and critically the special literature, the experimental and clinical data, the theories, current opinions, unsolved problems, and the general outlook of the subject." Each course will consist of eight monthly lectures, from October to May. The fee for each course is \$5; students of the department will be admitted free. Three courses will be offered during the coming session.

Good Work by Milk Inspectors in Chicago.—The Bulletin of the Chicago Health Department for the week ended April 9, says: During the week the laboratory analyzed 508 samples of milk and cream. Of these only 3.3% were found below grade. During this month the milk usually shows a larger percent below grade. The milk inspectors are directing their attention especially to the taking of shippers' samples and the examination of depots and dairies throughout the city. A complete list of all milk dealers and the condition of their dairies and wagons is being prepared. Those whose premises are found to be in an unsanitary condition will be given 15 days' notice to comply with the requirements of the department. At the end of that time, if the requirements have not been fulfilled, they will be denied a license when they apply on May 1.

Mortality of Michigan During March, 1904.—The total number of deaths returned to the Department of State for the month of March was 3,406, which was only 19 more than the number returned for the preceding month. The death rate for March was 16.0 per 1,000 population, as compared with 17.1 for the preceding month. Important causes of death were as follows: Tuberculosis of lungs, 227; other forms of tuberculosis, 43; typhoid fever, 57; diphtheria and croup, 38; scarlet fever, 31; measles, 27; whoopingcough, 21; pneumonia, 384; influenza, 156; cancer, 149; accidents and violence, 199. Deaths from pulmonary tuberculosis and typhoid fever showed some increase, while diphtheria and croup, pneumonia and influenza caused considerably fewer deaths in March than in February. By ages there were 527 deaths of infants under 1 year of age; 185 deaths of children aged 1 to 4 years, inclusive; and 1,159 deaths of elderly persons, 65 years and over. There were 3 deaths from smallpox—1 in Casnovia village, Muskegon county, 1 in Leonidas township, St. Joseph county, and 1 in Evert township, Osceola county.

CANADA.

Novel Method of Discouraging Drunkenness.—Habitual drunkards after conviction in Montreal, Quebec, are now given the option of paying a fine, undergoing imprisonment, or taking a certain cure. At present there are 22 under treatment, 10 at their homes and 12 at the jail. Each patient is expected to take 16 doses of the prescribed medicine each day, and is warned not to drink any intoxicating liquors during the time of trial.

FOREIGN NEWS AND NOTES

GENERAL.

Little Alcoholism in Italian Army.—Alcoholism is extremely rare in the Italian army. In the year 1901, the latest for which figures are available, only 25 cases were admitted into the hospitals.

Plague in South America.—Information April 13 says: The bubonic plague is spreading to an alarming extent along the west coast of South America. The State Department today received a cablegram from United States Minister Wilson at Santiago de Chili, saying that an extensive epidemic is raging at Antofagasta. This is one of the most important shipping ports on the west coast north of Valparaiso. The Public Health and Marine-Hospital Service will be advised so that suitable precautions may be taken at quarantine.

Control of Medicines.—Germany has passed strict laws to protect her people from the impositions of patent medicine manufacturers, but these have not effectively accomplished the object. Sweden, on the other hand, regulates the number of druggists, of which there are only 350 in the entire kingdom. In Stockholm there is only one druggist to each 15,000 inhabitants. The Swedish apothecary is a highly respected member of the community, being classed as professional men and acting in conjunction with local municipalities as public health officers. No medicine can be imported into Sweden except upon requisition of a druggist, and as it is considered unprofessional and improper to handle patent medicines their sale is practically, if not absolutely, debarred.

Disease in the West Indies.—Recent information from London states: At a meeting in London of the West India Committee, held recently, a paper on "The Disease Problem in the West Indies" was read by Sir Patrick Manson, who said that the list of West Indian diseases included all the diseases of Europe, with some two or three dozen tropical diseases. A hopeful feature about many of the diseases lay in the fact that they knew the cause of most of them, especially of those composing the tropical section; or, if they did not know their causes, they recognized the conditions under which those causes were applied. With regard to malaria, he said its parasite was passed from the sick to the sound by a special kind of mosquito, and said that if that mosquito were prevented from biting the sick, or if it did chance to bite the sick, from subsequently biting the sound, there would be no spread of the infection.

Children Suffocated in Bed.—Within the past 10 years over 15,000 infants in England have died from suffocation in bed from negligence on the part of the nurse or mother. In discussing this fact, *Il Politecnico*, of Rome, notes the comparative rarity of such occurrences in Italy, France, and the Teutonic lands. For a time, in Germany, the law prohibited mothers from sleeping with children of less than 2 years. Though this is no longer in effect there is a clause with penalty for contributory negligence. An English jurist has said: "Without doubt, there is an intimate relation between infant mortality and the frequency of drunkenness among women." The proof of suffocation can not as readily be adduced if the child be a weak one, or quite young. Evidence of a struggle, or of the results of convulsions, is possible in certain cases; nevertheless, the seriousness of the charge, with the uncertainty of facts, more often prevents legal interference.

Treatment of Sewage.—In a paper read before the Royal Institute of British Architects, Professor Clowes discusses the application of the biologic method of sewage treatment to the sewage of Christ's Hospital, at Horsham. The plant consists of closed septic tanks, into which the sewage flows by gravitation, from whence the effluent is distributed over the surface of coke beds, the liquid remaining in the bed for two hours and then passing away as the purified effluent through drainage channels in the bottom of the beds. No hitch whatever has occurred in the working of the plant, and on one occasion only has the smell been detected, the cause being stagnation during a lengthy vacation. Attention is called specially to this occurrence and to its cause, as it probably explains why similar installations for the treatment of sewage from isolated buildings have become offensive. The solid matter is absolutely disposed of in the septic tank; the number of bacteria in the effluent is 32% less than in the crude sewage, and the effluent will support fish life.

To Photograph Background of the Human Eye.—According to a German exchange, the assistant of the University Clinic of the Royal Charity Hospital, Dr. Walther Thorner, has succeeded in solving a problem which had received much attention from many others before him, but with little or no success. He has managed to photograph the background of the eye and obtain good pictures of it, too. His invention represents a material improvement on the ophthalmoscope invented by Helmholtz, in 1850. The latter, however, only admitted of viewing the background of the eye. The fact that all attempts to photograph the interior of the background of the eye had remained fruitless so far, was due to the peculiar construction of the eye. It is difficult to light up the interior to such an extent as to enable one to take a photograph of it, and even in the use of strong sources of light the exposure would require so much time that the eye would have to be fixed, which would mean great inconvenience to the patient. Now Dr. Thorner has constructed an apparatus with which he first succeeded in photographing the eyes of animals, especially cats.

Health of the British Navy.—The statistical report on the health of the British navy for 1902 has been issued, and is considered, on the whole, satisfactory. The total number of deaths was 590, as compared with 526 in 1901. The highest death-rate was on the Pacific Station, where it was as high as 67.42 per 1,000; not, however, from sickness, but owing to the loss with all hands of the Condor. The station, indeed, showed the lowest sick-rate of any. The highest sick-rate was on the East Indies Station, where it was 44.27 per 1,000. The irregular force with 43.03 ran it very close, however. The total number of cases of disease and injury entered on the sick list was 85,769, and the average number of men sick daily 3,523.39. Of the deaths, 350 were from disease and 240 from injury. Wounds and injuries were responsible for 16,383 cases, resulting in 225 deaths, and diseases of the digestive system were responsible for 13,614, resulting in 27 deaths. Only 2 wounds in action are recorded, with 1 death; only 1 case of plague, which terminated fatally; and 5 cases, 4 fatal, of cholera on the China Station. The total force serving afloat was 99,600, and the average loss of service from disease and injury represented 12 days for each person.

New Mosquito Disease.—According to Dr. Graham, of Beirut, another disease is to be set down against the mosquito, namely, dengue fever, variously called African fever, break-bone fever, giraffe fever, dandy fever, etc. The disease is an acute eruptive fever, rarely fatal, but leaving various disagreeable sequels—paralysis, insomnia, marked mental and physical prostration, etc. It occurs in hot climates and in the Southern States; during the last 50 years several serious epidemics have occurred. Dr. Graham found that he could regularly produce an attack of dengue in a nonimmune by submitting the latter to the attack of mosquitos which had fed on sufferers from the disease. In one experiment he carried dengue-infected mosquitos to a mountain town 3,000 feet in altitude, where there were no mosquitos and no dengue. One of the natives was shut up in the room with the mosquitos, and on the fourth day came down with a sharp attack of dengue, and a second presented the typical symptoms on the fifth day. The mosquitos were immediately destroyed, and no further cases occurred. Dr. Graham also claims to have discovered the germ which causes dengue in both human blood and the stomach of the mosquito. It resembles some forms of the malarial parasite.

Hygiene of the Japanese.—The *British Medical Journal* says that the Japanese themselves attribute their high average of physical strength to a plain and frugal diet, and the system of gymnastics called jiu-jitsu, which includes a knowledge of anatomy and of the external and internal uses of water. Although during the period of their ascendancy the Samurai kept the secret that their great physical superiority was due in a great measure to the internal and external use of water, the belief that if used liberally and intelligently water is an infallible weapon against disease is now generally held. By those who go in for jiu-jitsu an average of one gallon a day is drunk. It is noteworthy that rheumatism is almost unknown in Japan; it is probable that the absence of meat from the diet, combined with the use of plenty of water, accounts for this immunity.

Bathing is indulged in frequently, even by the poorest. In the matter of diet they are frugal to a degree, rice being the staple food in every Japanese house, and appearing at every meal. Japanese troops have often made record marches on a diet consisting solely of a little rice. The Japanese appreciate above all things the value of fresh air; night and day they keep their windows open and their rooms ventilated, and they do not fear draughts or damp air. Breathing exercises are an important part of their physical training—deep, careful breathing, which is only acquired by practice.

OBITUARIES.

Sir Henry Thompson, in London, April 19, aged 84. He was 79 years old when a baronetcy was conferred upon him by Queen Victoria. He was a surgeon and physician of fame, an artist who had 15 pictures in the Academy and the French salon, a novelist, the author of a most remarkable book on cooking, and in addition made more or less stir in several scientific branches of effort. He performed the operation upon Emperor Napoleon III, which resulted in the latter's death, and caused a bitter controversy. Sir Henry, however, boldly placed the blame for the death upon Sir William Gull, the Emperor's physician, who prescribed a fatal dose of chloral for the patient. The operation had been a success and results were all favorable. Napoleon objected to taking the chloral, but yielded to the persuasion of the Empress.

Lorenzo J. Kohnstamm, in New York City, April 12. Two years ago he had noticed symptoms of paresis, and without informing anyone he began a study of his case. When he had confirmed his suspicions he relinquished his practice, sold his art collection, and then, as the fight became hopeless, settled his affairs, and went to Bellevue Hospital, where he died of a general paralysis, ending in insanity. Dr. Kohnstamm was educated in this country and Europe, and was a member of the Medical Societies of Paris, Vienna, Brussels, and Berlin.

Samuel Smiles, surgeon, journalist, and man of affairs, in London, April 15. He was born at Haddington, Scotland, in 1812; was graduated from Edinburgh University, practised medicine for six years and then became a journalist and author. His writings have been extensive and popular. His "Self-Help," "Lives of Engineers," "Life of John Murray," "Character," "Duty," "Thrift," "Industrial Biography" and many others are well known and served to make the eminent Scotchman famous.

Clinton Joseph Schaaadt, of gastritis and nephritis, at the home of his parents in Egypt, Pa., April 4, aged 40; a graduate in the arts at Muhlenburg College in 1887, and of the University of Pennsylvania in 1890. For 11 years he was ship surgeon for a transatlantic steamship company, serving on the St. Paul, New York, and Paris.

Charles Gilbert Chaddock, at his winter home in Berkeley, Cal., April 1, aged 76; a graduate of the University of Michigan in 1885; member of the American Medical Association, of the St. Louis Medical Society; and professor of nervous and mental diseases in the Marion-Sims-Beaumont Medical College, St. Louis.

Narcissus Hereu Matas, at the home of his son Dr. Rudolph Matas, in New Orleans, April 13, 1904. Dr. Matas, the elder, was a native of Gerona, Catalonia, Spain, but came to the United States in 1856, after winning honors at several European universities. He resided for a number of years at Tucson, Ariz.

John Higgins, at his home in Crown Point, Ind., April 8; a graduate of the Indiana Medical College, at La Porte, Ind., in 1846. He served through the Civil war as surgeon in the Twelfth Illinois Cavalry and was afterward chief of the Army Hospital at Washington.

Dennis D. Loop, at his home in North East, Erie Co., Pa., April 2, from apoplexy, aged 76; a graduate of the University of Buffalo in 1884; one time president of the Erie County Medical Society and a member of the Medical Society of the State of Pennsylvania.

Louis A. Crist, at his home in Scranton, April 3, of pneumonia, aged 33; a graduate of the University of Pennsylvania in 1896; member of the Medical Society of the State of Pennsylvania and of the Lackawanna County Medical Society.

Philip Bissell, late house physician to the New York Hospital, in that institution, April 10, of pneumonia, aged 28; a graduate of Columbia University and of the College of Physicians and Surgeons.

Josiah C. Campbell, at his home in Attleboro, Mass., from pneumonia, March 24, aged 60; a graduate of Howard University, Washington, D. C., in 1877, and one time member of the Vermont Legislature.

George G. Griffin, at his home in Covington, Ga., April 4, aged 60; a graduate of Jefferson Medical College in 1859, and surgeon in the Confederate Army during the Civil war.

John Albert Gray, of Scottville, Mich., in Dallas, Texas, from pulmonary tuberculosis, April 3, aged 28; a graduate of the University of Michigan in 1902.

Floyd F. Hollister, of Weedsport, N. Y., at the home of his father in Mexico, N. Y., March 28; a graduate of Syracuse University Medical College in 1900.

Azariah Judson, of influenza and heart disease, at his home in Athens, Pa., March 3, aged 82; a graduate of the Berkshire Medical College in 1848.

Atticus G. Whitehead, at his home in Waynesboro, Ga., March 24, aged 63. He was twice president of the Medical Association of Georgia.

Henry G. Souder, at his home in Woodstown, N. J., April 1, aged 58; a graduate of Hahnemann Medical College, Philadelphia, in 1875.

Charles M. Garrison, at his home in St. Louis, March 26, aged 45; a graduate of the College of Physicians and Surgeons, N. Y., in 1884.

Francis Rush Skinner, at his home in Eau Claire, Wis., March 28, aged 72; a graduate of Castleton Medical College, Vermont, in 1854.

Edson S. Munger, at his home in Windsor, Vt., from pneumonia, March 29, aged 47; a graduate of the University of Vermont in 1882.

Franklin S. Douglass, at his home in Scranton, Pa., March 5, aged 50; a graduate of the Medical College of Georgia, Augusta, in 1883.

Watters Burrows, at his home in Elizabeth, N. J., April 2, aged 75; a graduate of the College of Physicians and Surgeons, N. Y.

William J. Gillespie, at his home in Philadelphia, Pa., March 14, aged 35; a graduate of the Jefferson Medical College in 1890.

William A. E. McKee, at his home in New York City, March 23; a graduate of the University of Maryland, Baltimore, in 1883.

John L. Gleason, Hannibal, Mo., in a hospital in St. Louis, March 30, aged 66; a graduate of Harvard Medical School in 1866.

Charles R. Sexton, at his home in Birmingham, Ala., April 2, aged 53; a graduate of Tulane University in 1875.

Rufus K. Hinton, at his home in Philadelphia, Pa., April 4, aged 74; a graduate of the Jefferson Medical College in 1852.

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended April 15, 1904:

SMALLPOX—UNITED STATES.		Cases	Deaths
California:	Los Angeles.....Mar. 28-Apr. 2	2	
	San Francisco.....Mar. 28-Apr. 3	1	
Illinois:	Chicago.....Apr. 2-9	8	1
	Danville.....Apr. 2-9	4	
Iowa:	Des Moines.....Apr. 2-9	1	
Louisiana:	New Orleans.....Apr. 2-9	2	
One imported.			
Maryland:	Baltimore.....Apr. 2-9	1	
Michigan:	Grand Rapids.....Apr. 2-9	2	
Missouri:	St. Louis.....Apr. 2-9	11	
New Hampshire:	Manchester.....Apr. 2-9	1	
New Jersey:	Camden.....Apr. 2-9	2	
	Trenton.....Apr. 2-9	2	
New York:	Buffalo.....Apr. 2-9	2	
Ohio:	Cincinnati.....Apr. 1-8	3	
	Cleveland.....Apr. 1-8	3	
	Dayton.....Apr. 2-9	4	1
Pennsylvania:	Johnstown.....Apr. 2-9	1	
	Philadelphia.....Apr. 2-9	20	5
	Pittsburg.....Apr. 2-9	5	1
One imported.			
South Carolina:	Charleston.....Apr. 2-9	4	
Tennessee:	Nashville.....Apr. 2-9	2	
Wisconsin:	Milwaukee.....Apr. 2-9	2	

SMALLPOX—INSULAR.		Cases	Deaths
Philippine Islands:	Manila.....Feb. 13-20	1	

SMALLPOX—FOREIGN.		Cases	Deaths
Africa:	Cape Town.....Feb. 6-13	3	
Argentina:	Buenos Ayres.....Feb. 1-29	1	58
Austria:	Prague.....Mar. 12-19	1	
Brazil:	Rio de Janeiro.....Mar. 6-13	45	30
Canada:	Winnipeg.....Mar. 26-Apr. 2	4	
China:	Hongkong.....Feb. 21-28	2	
	Shanghai.....Feb. 27-Mar. 5	6	
Colombia:	Barranquilla.....Mar. 21-27	1	
France:	Paris.....Mar. 19-26	16	1
Great Britain:	Dundee.....Mar. 12-19	4	
	Edinburgh.....Mar. 19-26	5	2
	Glasgow.....Mar. 25-Apr. 1	18	2
	Leith.....Mar. 19-26	10	1
	London.....Mar. 19-26	54*	
	Manchester.....Mar. 19-26	12	
	Newcastle-on-Tyne.....Mar. 19-26	3	
	Nottingham.....Mar. 19-26	11	1
	South Shields.....Mar. 19-26	1	
India:	Karachi.....Mar. 6-13	14	3
Japan:	Nagasaki Ken.....To Mar. 8	27	
Mexico:	Vera Cruz.....Apr. 2-9	1	
Russia:	St. Petersburg.....Mar. 12-19	9	5

YELLOW FEVER.		Cases	Deaths
Brazil:	Rio de Janeiro.....Mar. 6-13	6	1
Ecuador:	Guayaquil.....Mar. 12-19	1	4
Mexico:	Vera Cruz.....Apr. 2-9	1	

CHOLERA.		Cases	Deaths
India:	Madras.....Mar. 5-11	2	
Turkey in Asia:	Basra.....Mar. 26-31	5	7

* Erroneously reported April 9, as 84.

PLAGUE.

Africa:	Cape Colony.....Mar. 5-12	6	3
	Transvaal, Johannesburg.....Mar. 20		8
Australia:	Sydney.....Mar. 10	1	
Brazil:	Rio de Janeiro.....Mar. 6-13	4	1
Egypt:	Port Said.....Mar. 18	1	
Formosa:Feb. 29-Mar. 6	96	49
Mauritius:Mar. 3-10	3	

Changes in the Medical Corps of the U. S. Army for the week ended April 16, 1904:

WALL, F. M., contract surgeon, is granted leave for one month, from about April 1.

BARRY, EDMUND, contract surgeon, is granted leave for one month.

SLATER, ERNEST F., contract surgeon, is granted leave for twenty days, from April 10.

MOSELEY, Lieutenant-Colonel EDWARD B., deputy surgeon-general, leave granted February 23, is extended three months and he is granted permission to go beyond sea.

POWELL, First Lieutenant WILLIAM A., assistant surgeon, is relieved from duty as surgeon on the transport *Thomas*, to take effect upon the next arrival of that transport at Manila, P. I., and will then report to the commanding general, Philippine division, for assignment to duty.

KINCAID, KENNETH G., sergeant first class, as soon as his services on transport *Summer*, New York Harbor, are no longer required aboard that vessel he will proceed to the Presidio for duty.

FORD, First Lieutenant CLYDE S., assistant surgeon, is granted leave for twenty days.

KUCH, HERMAN, sergeant first class, is relieved from duty in the office of the chief surgeon and assigned to duty in the office of the attending surgeon at headquarters department of California.

HOFF, Lieutenant-Colonel JOHN VAN R., deputy surgeon-general, the seven days' leave granted is extended twenty-three days.

Changes in the Medical Corps of the U. S. Navy for the week ended April 16, 1904:

PARKER, E. G., passed assistant surgeon detached from the *Adams* and ordered to the *Wheeling*—April 11.

ODELL, H. E., passed assistant surgeon, detached from the *Wheeling* and ordered to the *Adams*—April 11.

DEVRIES, J. C., acting assistant surgeon, resignation, accepted to take effect April 11, 1904—April 11.

GREEN, E. H., medical inspector, detached from duty as fleet surgeon of the Asiatic fleet and ordered home to await orders—April 12.

DRAKE, N. H., surgeon, detached from the *Maine* and ordered to the *Lancaster*—April 12.

KITE, I. W., surgeon, detached from the *Navy Yard*, Norfolk, and ordered to the *Maine*, April 24—April 12.

WOODWARD, J. S., assistant surgeon, detached from the *Naval Proving Grounds*, Indian Head, Md., and ordered to the *Brooklyn*—April 12.

GILL, J. E., assistant surgeon, detached from the *Naval Museum of Hygiene and Medical School*, Washington, D. C., and ordered to the *Kearsarge*—April 12.

LUMSDEN, G. P., surgeon, detached from the *Naval Recruiting Station*, Chicago, Ill., and ordered to the *Navy Yard*, Norfolk, Va.—April 13.

BIDDLE, C., surgeon, detached from the *Lancaster* and ordered to the *Asiatic Station*, via *Solace* for fleet surgeon on board the *flagship*—April 13.

KENNEDY, J. T., passed assistant surgeon, detached from the *Naval Academy* April 26, and ordered to Washington, D. C., April 28, for duty to accompany Marine detachment to the *Louisiana Purchase Exposition*, St. Louis, Mo.—April 13.

WISE, A. H., acting assistant surgeon, detached from the *Naval Hospital Naval Home*, Philadelphia, Pa., and ordered to the *Naval and Marine Rendezvous*, Chicago, Ill.—April 13.

MCCULLOUGH, F. E., passed assistant surgeon, ordered to the *Wisconsin*—April 13.

SMITH, C. G., assistant surgeon, detached from the *Newport* and ordered home to wait orders—April 14.

CAMPBELL, F. E., assistant surgeon, detached from the *Naval Museum of Hygiene and Medical School*, Washington, D. C., and ordered to the *Newport*—April 14.

Changes in the Public Health and Marine-Hospital Service for the week ended April 14, 1904:

GREENE, J. B., passed assistant surgeon, granted extension of leave of absence, on account of sickness, for sixty days from February 25—April 2, 1904.

WARREN, B. S., assistant surgeon, granted extension of leave of absence for one day—April 11, 1904.

WARD, W. K., assistant surgeon, granted extension of leave of absence for four days from April 7—April 8, 1904.

STILES, C. W., chief of division of zoology, detailed to attend meeting of Medical Association of Mississippi at Jackson, Miss., April 20-22—April 12, 1904.

GREGORY, G. A., acting assistant surgeon, granted leave of absence for three days from April 12—April 12, 1904.

JACKSON, J. M., acting assistant surgeon, granted leave of absence for five days from April 20—April 12, 1904.

RODMAN, J. C., acting assistant surgeon, granted six days' leave of absence from April 12—April 9, 1904.

Board Convened.

Board convened to meet at Stapleton, N. Y., April 18, 1904, for the physical examination of an officer of the Revenue Cutter Service. Detail for the Board: Surgeon Preston H. Balhache, chairman; Passed Assistant Surgeon A. C. Smith, Recorder.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

A NEW GRAPHIC TEMPERATURE CHART.¹

BY
ROGER S. MORRIS, A.B., M.D.,
of Ann Arbor, Mich.

Instructor in Medicine at the University of Michigan, Ann Arbor.

There are many cases, in private practice as well as in hospital work, in which it is necessary to make frequent observations of the temperature, and of the various ways of recording it, the graphic method is by far the most convenient and time-saving for the physician.

Numerous charts for the graphic representation of the temperature have been brought forward, and it may seem superfluous to make additions to the long list. Still, there are few things which cannot be improved, and I was struck by certain advantages in a chart, used in the Baracken für Infektionskrankheiten at the Charité, Berlin, which served as the basis upon which the present chart was modeled. As may be seen from the accompanying figure, the chart may be used to represent not only the temperature curve, but also those of the respiration and the pulse, a thing which can be readily accomplished by the use of different colored inks or by various lines,

is also made at the top of the chart for tabulating the quantity of urine and the number of stools passed during each 12-hour period, while immediately above these spaces the date and the day of the disease are to be placed. Each chart is good for 10 days. Ample space has been reserved for the name of the patient, diagnosis, treatment, etc., while beneath the pulse and respiration record a considerable margin has been left for notes. The latter feature may appear unnecessary for hospital cases, but in private practice in which it is not possible to keep such complete records, any important clinical data may here be conveniently noted by the nurse in charge. The chart measures 11x17 inches.

CAUSE OF INCREASE IN PNEUMONIA.

BY
J. N. HURTY, M.D.,
of Indianapolis, Ind.

To the Editor of American Medicine:—A study of the Indiana mortality statistics and the morbidity and weather reports, furnishes data which seem to give some light upon the cause of the recent marked increase in the pneumonia deathrate.

Comparing the periods made up of November and December 1900 and January and February 1901 as the first period, and November and December 1903 and January and February 1904 as the second period, I find that in the first there were 1,720 deaths ;

Admission No. _____ Name _____ Age _____			Diagnosis:		Treatment:		Termination of Disease:	
Admitted _____ 10 _____ Address _____								
Date _____ Day of Dis. _____								
Urine _____								
Stools _____								
Pulse _____ Resp. _____ Temp. _____								
210 _____ 107 _____								
195 _____ 70 _____ 106 _____								
180 _____ 10 _____								
165 _____ 80 _____ 104 _____								
150 _____ 103 _____								
135 _____ 50 _____ 102 _____								
120 _____ 101 _____								
105 _____ 40 _____ 100 _____								
90 _____ 99 _____								
75 _____ 30 _____ 98 _____								
60 _____ 97 _____								
45 _____ 20 _____ 96 _____								
20 _____ 95 _____								
Pulse _____								
Respiration _____								

such as broken, continuous, light, heavy, etc. Spaces are provided for recording 12 observations in the 24 hours, though it matters not whether more or fewer observations are made. The day hours (from 6 a.m. to 6 p.m.) are in white, the night hours in color (pale pink or light green). This fact possesses the great advantage that it permits the physician to see at a glance the exact relations of the fever curve to the time of day. In a remittent fever, for example, one sees at once whether the maximal temperature occurs during the day hours or during the night, and further, whether early or late in the day or night hours, as the case may be. In those cases in which it is not desired to make a graphic representation of pulse and respiration—and this, probably, is the rule, spaces are left at the bottom of the chart where the figures may be filled in. Provision

the weather was not severe, measles, influenza and "colds" were very prevalent and natural gas with no smoke was the almost universal fuel. The mild weather, and the use of soft coal, as suggested by Dr. Lindsley of Connecticut, were not the cause of the increase in pneumonia which appeared in the period named. In the second period, there were 1,784 pneumonia deaths, only 64 more than in the first, and the weather was very severe, soft coal was the universal fuel, and measles, influenza and colds very prevalent. It appears, therefore, that in the two periods separated by three years, they were closely alike in number of pneumonia deaths, also in the fact of prevalence of measles, influenza and "colds," but unlike in regard to weather and soft coal smoke. Further, it appears from an examination of the death certificates of the two named periods, that an unusual proportion of pneumonia deaths among children

¹ The chart is published by George Wahr, Ann Arbor, Mich.

occurred. For instance, in February 1904, of the 711 pneumonia deaths, 268 or 36.2% were under five years, and in February 1901 there were 608 pneumonia deaths, with 237 or 39% under five years. Such a coincidence under the circumstances is certainly noteworthy. In the two intervening Februaries, namely, of 1902 and 1903, we note fewer pneumonia deaths with blustering cold weather, plenty of coal smoke, but not a remarkable presence of measles, influenza and "colds" and a lower pneumonia deathrate among the children. So far as Indiana is concerned it would seem that the increase in pneumonia was due to the greater susceptibility caused by measles, influenza and "colds."

SOME ABNORMAL POSITIONS OF THE APPENDIX.

BY
ANDREW B. GLONINGER, M.D.,
of Lebanon, Pa.
Surgeon-in-Charge, Lebanon Sanatorium.

In February, 1904, I operated in two cases of appendicitis, in which I found the appendix in the hypochondrium. Both cases seemed to be unusual enough to report.

CASE I.—P. U., aged 6, was brought to the sanatorium by Dr. Strohm, of Fredericksburg, during an acute attack of appendicitis. We could obtain no history of a previous attack, but he had the appearance of chronic ill health. He was operated on a few hours after admission. After making the usual two-inch McBurney incision I found a walled-off cavity under my fingers, where I expected, of course, to find the appendix, but careful search failed to find it within reach. So I lengthened the incision upward, and following the cecum to its head, which was drawn up under the liver, I found the appendix imbedded in the posterior wall of the hypochondrium. I managed to free it intact, and amputate it in the usual manner, inverting the stump after the method of Dawbarn. The bed of the appendix was now a deep, ragged wound in the wall; I cauterized it thoroughly with carbolic acid, sutured the edges of peritoneum over it with fine catgut. I flushed the cavity with hot salt solution, and closed the incision with tier sutures of catgut, following the practice of Thierry in using metal clamps for the skin suture. The patient made an uneventful recovery and left the sanatorium in two weeks.

CASE II.—Miss S., aged 18, had her first attack two years before, when she was taken to the hospital for operation. The surgeon who made the section failed to locate the appendix and concluded that it had been absorbed, and left the family under the impression that he had removed it. For two years the patient suffered repeated attacks, growing more frequent and severe; these were considered by the family physician, Dr. John Light, of Cornwall, Pa., to be largely hysteric, until he learned the true history of the first operation and brought her to the sanatorium for an exploratory section. When admitted she was in a weakened nervous condition following an attack, and was operated on two days later. I made the incision in the median line to avoid the extensive cicatrix left by the first section in the right iliac. I found the conditions the same as in Case I, only the adhesions were more dense, and general, owing to the repeated attacks of inflammation. I had to lengthen my incision in order to reach the appendix easily, as it was adherent to the lateral wall on a level with the border of the liver. The patient is now convalescing rapidly.

CASE III.—An engineer, aged 40, inguinal hernia, strangulated while stepping from the car of locomotive; was admitted to the sanatorium at midnight and operated on at once, as he was suffering intense pain, even under the influence of mor-

phin. The hernial sac contained the appendix. The head of the cecum and 10 in. or 12 in. of small intestine were all highly inflamed. I amputated the appendix and opened the ring and returned the bowel, then closed the ring with mattress sutures of catgut reinforced with a figure of eight silkwormgut suture through the center of the ring, and all the walls, then leaving the sac intact, I sutured what muscle I could find and the internal fascia over it and after tying the one deep suture I closed the remainder of the skin incision with metal clamps.

I would like the opinion of the profession as to the cause of the condition in the first two cases. The patients were both the children of Pennsylvania farmers and as the custom is, were put to work at an incredibly early age, and at tasks far beyond their strength, and fed on fried ham, snitz pies, coffee, etc.; the 6-year old boy had been doing almost a man's work in taking care of stock. My idea that the constant straining of heavy lifting on undeveloped muscles falling chiefly on the muscles of the right side of the trunk, would gradually draw the head of the cecum upward and the intestinal irritability due to the diet would predispose to adhesive inflammation. These cases should also teach a few lessons to the young operator. For instance, after carefully finding his bearings and making the approved incision after the manner of McBurney he must not be discouraged if he does not find the appendix ready at hand as it should be. Also that less traumatism is done by the surgeon who, when he finds he has a difficult case opens the abdomen freely and gives himself plenty of room to work. Also Case II shows that we can not always bury our mistakes, or even our insincerities.

ORIGINAL METHOD FOR OBTAINING METRIC QUANTITIES.

BY
MATTHEW NEIL, M.D.,
of Honolulu, H. T.

Sergeant, Hospital Corps, United States Army.

To the Editor of American Medicine:—Perhaps the following will be of interest to some of your readers. It represents my original method for finding metric quantities when any number of liters or fractional parts of a liter be given in proportion of 1-? thousands.

Rule.—Divide the number of liters or decimal parts of the liter by the number representing the thousands.

EXAMPLES.

I.—3	liters of a 1-16,000	solution.	
3	÷ 16	=	.1875
II.—1½	liters of a 1-15,000	solution.	
1.5	÷ 15	=	.1
III.—360 cc. of	a 1-4,000	solution.	
.36	÷ 4	=	.09
IV.—750 cc. of	a 1-6,000	solution.	
.75	÷ 6	=	.125

If the work be done decimally the quotient will show the exact quantities expressed in grams or decimal parts, deci, centi or milli.

Should any other number of parts per thousands be required, multiply the quotient by that number.

PARTURITION DATES FOR THE LEAP YEAR, 1904.

BY
HENRY RICHTER,
of New York City.

First day of last menstruation.	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30	31
January																															
June																															
August																															
October																															
November																															
February																															
September																															
March																															
April																															
July																															
December																															
May																															

EXAMPLES:—First day of last menstruation, January 1; medium parturition (280 days), October 7 (not November 7).
First day of last menstruation, May 31; medium parturition (280 days), March 6 (not February 6).

THE RATIONAL TREATMENT OF MALIGNANT TUMORS.

BY

HOMER WAKEFIELD, M.D.,
of New York City.

The medical profession is at present confronted by a peculiar predicament. Great discoveries of science of astounding therapeutic value have been unfolded with such bewildering rapidity during the last decade, that we have failed to keep abreast with them in analyzing the nature of their true therapeutic actions, or in grasping the fundamental laws upon which must be founded a sound basis for their successful application. Results have been obtained in individual cases and in a group of diseases, largely taken from the supposedly incurable list, that proclaim remarkable therapeutic potency for physical agents of which we have heretofore been largely in ignorance. Able men have done much to elucidate the value of the several forms of radial activities, the technic of their administrations, and many other points of value tending to a general development of the subject.

Much research, also, has been devoted to the exposition of certain theories of pathogenesis, and I feel convinced that many have been led astray by misconceptions of the relation of microorganisms to disease, and of the effects of these therapeutic agents upon such organisms. Others again, have been misled by theories of disease, accepted more out of respect to their distinguished progenitors than to the intrinsic merit of the theory, *per se*. Thus we have for our consideration an enormous literature of clinical and experimental reports, presenting a multitude of diverse and conflicting theories of every phase of the subject.

The medical press is fairly teeming with articles and reports of the administration of röntgen ray, radium, and Finsen light treatment of malignant growths, together with results varying from the most humiliating failures to the most gratifying successes: Such uncertain results as would suggest the "shot-gun" prescriptions of primitive medicine. Malignant cases differ to some extent in their etiologic factors, vary somewhat in their pathology, and demand an intelligently adapted treatment, based upon a sound etiology and pathology. This is where the present treatments are weak and uncertain. They are almost entirely empiric, *i. e.*, they are applied too blindly, with too little regard to any definite idea of their causation or of the nature of the conditions presented. It is too much of a "catch as catch can" conflict, and the diverse results are not creditable to our profession, in this enlightened era. The treatments are as imperfect as they are new; and in empiricism they are unsurpassed by any other known to us. I believe the imperfections of those therapeutic agents are not due to their impotency or inconstancy, but entirely to the lack of proper adaptation and to general irrational therapeutics.

If physicians will examine their patients thoroughly for evidences of *katabolic stasis* and its causative factors in cases of malignant growth, as I have enumerated them in *American Medicine* a year ago,^{12b} and adapt the treatment to the eradication of these expressions of subkatabolism, I am convinced that they will reduce the therapy to a definite scientific basis. These etiologic factors may be always observed in the case history. The morphologic and other evidences of subkatabolism will always be found present, when an effort is made to bring them to light, and moreover the skilful administration of the therapeutic agents already at our disposal will be found entirely adequate to meet the indications.

It is not to be inferred that the extra deep neoplasms which cannot be reached by radiointensifying agents, can be treated as successfully as the more superficial ones, but the ununiform results now obtained in similar

types, may be made uniform and to bear relation to the general medical knowledge, resources and skill of the therapist.

Another "short-coming" of cancer therapeutists, is that unlike the up-to-date practitioner of general medicine, too many of them are *faddists*. One man's fad is the röntgen rays; another's, radium; another's, cataphoresis; another's, high-frequency currents; another's, the knife; and so on; but few of them base their treatments on any definite idea of what cancer is, or what they are accomplishing by their "pet measures," and but few attempt to do anything for their patients, outside of the particular treatment upon which they specialize.

In my efforts to institute a reform in the plan of treatment among the New York profession, my greatest "bugbear" has been the difficulty in impressing the importance of breaking away from the empiric plan, and in treating cancer on the general plan usual in other diseases.

One trouble, and a cause of the present difficulties, is the fact that men interested in cancer are now specialized in diverse lines as gynecologists, surgeons, electrotherapeutists, dermatologists, and perhaps occasionally general practitioners who have procured tubes of radium, static machines, or coil apparatuses. Many have rushed headlong into these lines upon the strength of evidence of occasional success in the hands of others—many of these men are optimistic one day and pessimistic the next.

Symposiums and discussions on the subject given before our medical societies, are remarkable for their diversity of theory, practice, and results obtained.

With a view of facilitating the analysis of the etiology of neoplastic diseases and of simultaneously illustrating the essential subkatabolic elements underlying the divers modes of origin and of developmental stages of the case histories, I beg to direct attention to correlations of the several recognized antecedent diseases, their nature and relations to katabolic stasis and the resultant malignant states. Neoplasms not infrequently occur as sequels of anemia, chlorosis, leukemia, pseudo-leukemia, rheumatism, gout, scrofula, syphilis, leprosy, malaria, tuberculosis, diabetes, gastrointestinal, cardiac, renal, and other organic, and so-called diathetic diseases, which as precursors, produce or result from suboxidation, as it may be induced in individual cases by suboxygenation or by hyperacidity or oxidase deficiency. Suboxygenation produced by the incidental destruction of red cells and hemoglobin during the progress of any of these diathetic diseases, is identical with that caused by hemorrhages, which by diminished volume of the whole blood, acts the same. For example, respiratory diseases of long duration, as chronic bronchitis, emphysema, pulmonary tuberculosis, bronchiectasis, asthma, pneumothorax, etc., are thus singly and in combination causative factors of suboxygenation. Various occlusions of the nasal, postnasal and pharyngeal spaces, by chronic swellings, tumefactions, etc., are not unimportant. Suboxygenation from any one or more of the foregoing factors should be significant etiologically, and moreover their identification suggests *per se* the nature of the therapy demanded. Vitiating atmospheres also must be remedied as they occur.

There are, however, other compromisers of oxygenation, both as primary causes and as secondary complications. Among the former may be mentioned the hypercombustion of food, beverage and drug products, in the liver, which by consumption of an excess of available oxygen deprives the tissues. The ingestion of various alcoholic liquors as beverages, highly concentrated and oxidizable carbohydrates as foods; and lead, arsenic, antimony, mercury, copper and phosphorus (in sufficient doses) as drugs, may be easily demonstrated by any practitioner, as suboxidizers, by their actions as counter-oxidants of high degree. Another instance of perverted oxidation is that of intestinal putrefactions, fatty, acid

and other suboxidated products, which by their super-oxidation, cause tissue suboxidation. These conditions are amply exemplified by the high temperature on the one hand and the tissue suboxidation on the other. Such vicious cycles, in prolonged high fevers, are actually demonstrated by the fatty degeneration of suboxidated tissues, the circulating products of which are carried to glandular structures where they supply the fuel for the continuation of the perverted hyperoxidation.

Another important source of suboxygenation, which must not be neglected in the search for etiologic factors, is in the circulation of the blood. The insufficiencies of the heart first attract attention. Orificial stenoses, valvular deficiencies and muscular incompetencies, from all causes, owing to a diminished blood output, are important factors of suboxygenation. Next in order should be considered the vascular system, for diminished arterial caliber (congenital and from arteritis), arterial and capillary occlusions from tetanic contractions of their muscular coats from autotoxemias, from thrombi and emboli (solid and colloid) and arteriocapillary fibrosis and arteriosclerosis. Atheroma, gelatiniform vascular dilation, pressure by various bodies and the congestions of traumatisms, abnormal distribution of the blood, as in the splanchnic engorgements of venous stases, and as caused by fright, shock, cold, etc., which may become chronic conditions when not treated or when improperly treated. The examination of the vascular system, of course, must include a careful inspection of the several blood glands of the body, as the liver, kidneys, spleen, adrenals, pancreas, thyroid, thymus, pituitary body, lymphatics, etc., by means of physical signs and of the several manifestations, by which their pathology is identified. When all of these possible factors of suboxygenation are thoroughly covered, the physician may proceed to examine into the causative factors of *suboxidation*. After the exclusion of the foregoing factors, a most careful examination must be made for those that are to follow. And even if one or more of these are convicted of complicity we are not justified in excluding the following of coexisting; so a successful therapy demands that the rigid examination proceed.

During the critical periods in the life of woman, namely, puberty, menstruation, pregnancy, parturition, the puerperium, lactation and the climacteric, she will manifest an exacerbation of any existing subkatabolic diseases, and this will be especially pronounced when due largely to *oxidase* defects. In this relation, the diseases of the large glands and lymphatics, the time relation of the occurrence of malignant growths in women, especially when of the uterus, vagina, ovaries or breasts, to sexual obsolescence, and particularly in women who have undergone many pregnancies in more or less rapid succession, and have suffered impaired general health as a direct result, are foremost. Anyone who may question the intimate relation of these periods with subkatabolism in general, will do well to observe and consider their other suboxidative manifestations, for they all may be identified as identical with those of recognized hyperacidity, suboxygenation or suboxidation, occurring otherwise. The subkatabolism of puberty and adolescence is occasionally also manifested by adiposity, obesity, joint pains, insanity, etc.; that of pregnancy by anemia, leukemia, chlorosis, chorea, epilepsy, insanity, malaria, albuminuria, goiter, eclampsia, rheumatism, pulmonary tuberculosis, multiple neuritis, neuralgia, osteomalacia, uremia, gingivitis, icterus, varices, cardiac diseases, hemorrhages, paralysis, cutaneous disease, leukorrhea, etc.; the puerperal period by malaria, insanity, albuminuria, eclampsia, multiple neuritis, etc.; that of lactation by progressive pernicious anemia, leukemia, osteomalacia, etc.; that of the menopause by arthritis deformans, insanity, anemia, menorrhagia, visceral congestion, hemorrhoids, scrofulosis, cancer, chlorosis, gout, chronic rheumatism, neuralgias, nervous

debility, obesity, paraplegia, hysteric or epileptoid manifestations, etc.

Many diseases and conditions which are *secondary* to others mentioned, may be present, though not herein enumerated; for example the typical features of anemia, etc. The observed relations noted, occur in various relations as both resulting and complicating. In the latter cases exacerbations are observed to occur during these critical periods. A condition that is common to both of these states, though of varying intensity, is a general gelatiniform depravity of the tissues, not infrequently resulting in an individual or general organoptosis, affecting one or more of the abdominal or thoracic organs, as individually influenced by local causes, as strain, fatigue, etc.

Local causes of malignant tumors, however important and essential to the determination to a particular site, must be dependent upon a general subkatabolism (the constitutional condition) to perpetuate and insure the characters of malignancy.

There are several causes of general subkatabolism, other than those of the critical periods of life, for instance, those enumerated, which produce both suboxygenation and suboxidation, and which operate and cooperate with each other in both sexes; they are sexual excesses and vices which by oxidase exhaustions diminish oxidation. Worry and anxiety cause indigestion, insomnia, "nervous debility" and secondarily arteriosclerosis, arthritis deformans, cardiac lesions and degenerations, insanity, diabetes, exophthalmic goiter, gout and degenerative (subkatabolic) changes of the blood elements. Great and sudden grief, intense emotion, distressing disappointments, sudden chill and fright, like trauma, often partake of the elements of shock, which amounts to the addition of another factor of suboxidation. Fatigue is a factor of subkatabolism, hence also of cancer; its effects are especially prominent when observed in complication with other factors as in chorea, hysteria, neurasthenia, mountain sickness, cold, etc. The effect of strain is exemplified in the relaxation of the abdominal walls, in the etiology of hernia, the determination of gouty and neoplastic processes to places of strain, as the articulations of the great toe, etc.

Mental and physical overwork and loss of sleep exhibit an accumulation of fatigue products (sarcolactic acid) in excess of the oxidative processes of recuperation, thus producing suboxidation by hyperacidity.

Traumatism bears an intimate etiologic relation to a great number of diseases involving subkatabolism, including appendicitis, arthritis deformans, diabetes, epistaxis, gout, hematuria, nephritis, hysteria, leukemia, scleroderma, shock, tuberculosis, susceptibility to infection, lymphangitis, insanity, cancer and sarcoma. Pressure will readily be recognized as an inhibitor of oxidation, by its occlusion by collapse of the vascular canals. All surgical pathologists recognize pressure as a cause of degeneration of the involved tissues. Irritation has long been recognized as one of the most prolific local causes of malignant tumors as well as of many lesser subkatabolisms. It may be broadly stated that all rudimentary protoplasm and cell life, in general, attains adulthood in direct ratio to its immunity or protection from irritation; and conversely, by irritation, adult tissues of however high organization may be reduced to a homogeneous colloid mass.

Let us take as an illustrative analogy, such naked unicellular organisms as the ameba and the marine rhizopods. These are the closest analogs of the leukocytes, and being unprotected by an investing membrane, they are continually in the gelatiniform state. When normally oxygenated they are relaxed and exhibit extended pseudopods. While in this state they present the normal attribute of nutritive phagocytosis, exhibiting selective faculties for food. When a pseudopod comes in contact with a food particle, the contact stimulus causes an increase in the protoplasm of the pseudopod to occur,

until the food particle is, if possible, surrounded or englobed by the jelly-like protoplasm.

Conversely, instead of that of a food particle, the contact may be an irritative one, or the contact effect may be a shock in place of a stimulus, and instead of a "streaming" of the protoplasm, as described, we observe a contraction or withdrawing of the pseudopod and the attainment of a spheric formation. Precisely the same effect may be attained by an environment free from oxygen, and moreover the restoration of relaxation and the reextension of the pseudopod may be obtained simply by the readmission of oxygen to the environmental atmosphere. The irritation effects mentioned may be produced by either mechanical or chemie irritants, by changing the medium from an alkaline, or neutral, to an acid reaction, by pressure, by contusion, shock or concussion, or a series of concussions, by stimulation to the point of fatigue, excessive light, heat and cold, electric shocks, poisons, etc.; anesthesia and narcosis cause irritation, secondarily, by suboxidation and the accumulated hyperacidity. According to the amount of any of these agencies affecting such cells, the protoplasm, as stated, undergoes contraction, and then, by water absorption, it becomes of a continually more fluid character; the protoplasm first delivers up its cell inclusions and finally the cytoplasm flows away from the nucleus. First disorganization, then disintegration intervenes. The nucleus lastly undergoes disintegration as a final step in the destruction of the cell.

Now to revert to the animal tissue cell, we find all the foregoing actions are produced by the same agencies. Moreover, we are permitted to study the effects upon a larger scale, for instead of unicellular organisms we observe the effects upon large areas of cellular tissues. The phagocytic functions of leukocytes are strikingly similar to the life habits of such unicellular organisms as I have alluded to.

Let us now consider the effects of these several cellular retarders and destroyers upon the economy as a whole. It matters little, except in time relation, which of these several agencies we use in our experiments; though duration, intensity and quantity are important factors, the manner of their production is not important, except in so far as they involve complicating factors, which vary or modify the results obtained. Whichever of these methods we adopt, we observe either locally or generally the same process of cellular liquefaction (gelatification) and finally disintegration, which characterizes the effect upon the unicellular organism; with the exception of the putrefaction of the liquefied protoplasm after necrosis in the unicellular organisms, which has not to my knowledge been studied. Next, to arrive at the essential nature of the common causative action, we are enlightened by the observation that analogous to the effect on the unicellular organism, namely the contraction of the protoplasm and withdrawal of the pseudopods, the first stage noted in vertebrate animals is a diminution of the C_2O output, diminution of urea, of phosphates, etc., and more or less leukocytosis, generally, and a hyperplasia or hypertrophy (locally) in spite of a more or less imperfect new cell formation (mitosis). The second stage (varying with the several elements) exhibits the retrograde process as the cells disintegrate by either liquefaction or putrefaction, which are so closely allied, the latter a partial or general necrotic change. With the attainment of this stage we observe an increase of urea, uric acid, phosphates, etc., and lastly a fall in the leukocyte index below normal, thus indicating their destruction in contrast to their earlier superannuation.

It is significant that all these factors are equally active and produce the same results on both unicellular organisms, and on the complex vertebrate, and all are the typical results of suboxidation in both instances. Thirdly, we may trace the pathologic effect of the several diseases of known origin, of any of these named agen-

cies, and the characteristic effects will be noted, conforming to the foregoing observations. Fourthly, it is observed that the restoration to the normal in all of these pathologic conditions is accomplished by, and only by, their logical counteraction as suboxidative processes. Lastly, now let us trace a curve of a true case of a developing subkatabolism and its "cure:"

A young married woman suffered a prolonged local irritation from a sharp fragment of a lower tooth, which produced a local ulcer, without tumefaction. Finally, she became pregnant, and as the pregnancy progressed, the ulcer became painful; then followed a tingling sensation, numbness, and finally anesthesia, which extended over the whole inferior maxilla. The local tumefaction extended it into a hard sarcoma, which doubled the size of the entire lower jaw. During this period the tumefied parts felt cold and lifeless, and the balance of the face almost feverish in contrast. After the parturition, the lactation was aborted, and the tumor was put under röntgen ray treatment. After the second treatment, the cold anesthetic parts changed to supernormal warmth, and sensation was restored. This was continued until the tumefaction gradually became reduced to nil, and the tissues resumed the normal appearance and action.

Other cases require other restorations of defective factors of oxygenation and oxidation, as alluded to elsewhere in this paper. Yet they all bear relation to the same etiologic processes.

All observers recognize diminution of body heat as an invariable indication of a failure of metabolic oxidation. Moreover, all recognize the main factors of sub-oxygenation, namely, deficient respiration, cardiac and vascular deficiencies, and impoverishment of the blood as causative factors; in fact, from such deductions there is no escape or alternative. From this point forward, however, there is an unfortunate diversity of conclusion between chemie physiologists and clinical pathologists, in the interpretation of experimental findings, many of which are absolutely incompatible with those of other men, in the same and in other lines of investigation.

It is observed that in my own researches I have taken as a basis fundamental facts that are generally accepted, enumerated before, and have drawn deductions from subsequent observations that are entirely compatible with all accredited facts, chemie, physiologic and pathologic, and moreover, also, biologic. In the same manner that the chemie analyst uses chemie reactions, the physiologist uses physiologic signs, and the bacteriologists use staining, toxic, and other reactions as indicators. I have based my conclusions largely upon comparative pathologic tissue changes, safeguarding them by building my hypothetic fabric according to the accepted laws of chemistry, physiology, pathology, and biology. I have, for example, found strong pathologic evidence to prove in some instances in which chemists are, by analysis of carbonic acid and other eliminations, unable to demonstrate tissue suboxidation, that normal and supernormal oxidations take place within the glandular system, the latter depriving the tissues of available oxygen, even though the average body combustion with its typical products is not diminished. I have found just as typical and constant pathologic results from the effects of acidity, subalkalinity, suboxidation, and from hyperoxidation, as are otherwise exhibited by chemie, biologic, or physiologic experiments. Moreover, my deductions also harmonize with the most approved of our conceptions of disease and their most successful therapy.

It may be mentioned that, for example, there are many adequate parasitocides that are not oxidants, which are impotent as cancer cures, yet oxidants are potent in ratio to their oxidation capacity. Thus, from our therapy, we find additional evidence regarding the nature of the malignant process.

Notwithstanding that pathologists quite universally identify disease processes by tissue changes, they quite as commonly look to physiologists for the study and interpretation of the nature of the processes, both from the chemie and physiologic-pathologic standpoint, and it is

a fact that physiologists quite universally perform their experiments upon, and compute their calculations from, observations of the lower animals, quite independent of the clinical pathology of the human subject. Thus diversities in deductions occur which are quite incompatible one with another. It is not my purpose to deprecate the great work that has been done and is now in progress, by research specialists, but to point out and emphasize the value of a more perfect amalgamation of these several lines of investigation, and to make a plea for the more general recognition of the value of clinical pathology in connection with the chemic physiology, chemic biology, and chemic pathology. Strictly speaking, clinical pathology should always include the foregoing branches, practically applied and adapted to the etiology, symptomatology, pathology, pathologic anatomy, and therapy of pathogenic processes.

It is my endeavor to direct the attention of the profession to the value of recognizing the significance of certain changes and unvarying indicators of definite metabolic states, as caused by certain definite chemic agencies.

In order to have a clear understanding of katabolism, it is essential that we have an equally good grasp of the physics and chemistry of oxidation; and to this end I will submit a few pertinent facts:

The metamorphosis which we term oxidation is characterized by different chemic changes, as it occurs with different substances and combinations, but in all instances one action is a common factor, namely, the combination with oxygen.

Now oxygen does not have a stable existence in the same form in which it combines, hence we say it has 2 allotropic forms, one the form in which it has existence in the free state, or ordinary oxygen, and the other, that in which it undergoes combination, active oxygen, or ozone, from which it always deteriorates into ordinary oxygen.

Ozone is much more radioactive than ordinary oxygen, and possesses a correspondingly greater density, which is half again as much as that of oxygen, and a molecular weight which is 3 times that of ordinary oxygen. Thus 3 atoms of ozone occupy the space of two of oxygen.

As oxygen combines only in the form of ozone, oxidation resolves itself as dependent upon measures which render oxygen active, or into ozone. Different substances oxidize at different degrees of heat, or at the point at which they are able to impart to oxygen the necessary radioactivity. Thus we may say that heat will bring about the oxidation of almost anything, if sufficient in quantity.

In the human and other warm-blooded animal bodies, we observe oxidation of substances at temperatures far below the points at which these substances ordinarily oxidize, hence we must conclude that other agencies beside heat must have to do with the transition of oxygen into ozone. Now if we search outside of the animal kingdom, we observe the same thing taking place, and the solution of its causation is simple enough. We observe that certain substances, as turpentine, and other essential oils; phosphorus (when prevented from burning), etc., will slowly oxidize and emit phosphorescence, and moreover, contiguous oxygen not combined, will be rendered active or transformed into ozone. Also, it is observed that certain chemicals (halogens), which by a great affinity for substances combined with oxygen, as hydrogen, set oxygen free which is then, as it was when combined—active; hence we identify nascent and active oxygen or ozone as indicating the same substance. All oxygen is active when first liberated.

Other activities cause oxidation to take place, and hence produce the necessary activity of oxygen, such as the so-called chemic rays of light, of the spectrum, from the blue to the ultraviolet, and including the post-refrangible rays, electric arcs, sparks and lightning, high-frequency currents, and the radioactive metals.

In the muscles of vertebrate animals is observed a most interesting application of this phase of the subject, in which oxidation is definitely connected with muscular cell activity and is correspondingly lowered by sedentation, etc. We have long made use of this knowledge in medicine, by enhancing oxidation by means of exercises and topical stimulation, as by massage, faradic and ordinary galvanic electricity.

We, however, have another means of augmenting oxidation, at normal body heat, and that is by the thickly studded nuclei of the cells of the several glandular structures, especially the essentially blood-glands, the acting nucleins, and the function being known by the name of oxidasis. In the activity of this function, phosphorus plays a part as an essential constituent of the nucleins, yet that does not prove that there is in this case an allotropic change incident to it, as occurs in pure yellow phosphorus, but rather the requisite radioactivity.

It is observed that oxidation, independent of the body, is dependent upon the presence of several factors, namely, the substance to be oxidized, the oxygen to oxidize it, and the oxidase, *i. e.*, the source of the radiointensification, which must be supplied by the combining substance or by a contiguous substance.

In the therapy of suboxidation in the human subject, my plea is for an intelligent administration of a supply of one or other of the factors of oxidation, as indicated, be they the necessary oxygen, the essential alkaline medium for oxidation, the restored normal oxidase elements (phosphorus) or an artificial radiointensifier, as may be imparted by ultraviolet light, röntgen rays, becquerel rays (radium, etc.), and high-frequency currents of electricity.

In shock and allied conditions there is a good illustration of suboxidation as caused by a sudden and extreme determination of the blood to the splanchnic vessels, thus largely vacating the peripheral vessels, especially of the muscles. And in sedentation and enforced immobility, types of a more graded, but possibly just as pronounced or even greater degrees of peripheral anemia with all its subkatabolic effects displayed on the whole body, or any part rendered immobile, that of shock being characterized by a more acute effect and greater general circulatory depression; while that of sedentation and enforced immobility exhibits a more pronounced and exclusive subkatabolism of affected muscles.

In a previous paper^{12a} I directed attention to the fact that approximately 36% only of the total blood volume of the body is contained in the various organs of locomotion during rest, the other 64% residing in the roomy reservoirs of the abdominal and thoracic cavities; conversely during activity as much as 64% of the total blood is deflected to the muscular system. When we fully grasp the significance of these facts, and with it the parallel increase of oxidation, associated with the augmented radioactivity of the tissue cells, we have some conception of the etiology of the several diseases of sedentation, the atrophy of immobility and of the suboxidative effect of the elements of shock, of muscular inactivity in general, and of chill and similar factors which serve to determine the blood from the periphery to the internal vessels.

We have seen that if any of the essential elements of oxygenation are absent or seriously interfered with, we have subkatabolism in spite of the fact that the other elements are entirely physiologic, the same with the elements of oxidation. Conversely we observe in the present instance as in the oxidase deficiencies, so commonly connected with the sexual life, that regardless of the oxygen capacity of the respiratory and circulatory systems, suboxidation and hence subkatabolism will result. The study of these factors also graphically pictures the reason why we fail to restore by oxygenation when oxidation is at fault, and conversely why we fail in certain cases to cure by supplying the immediate ele-

ments of oxidation, *per se*, when one or more of the factors of the supply of oxygen is at fault.

How often have we read the reports of observers who have condemned oxygen inhalations for their incompetency as "cure alls" of suboxidation, and it is notorious that neither experimental nor chemic observers have paid the slightest attention to any other factors, of either oxygenation or oxidation, *per se*, as individually subjected to experiment. This is equaled only by the still more universal custom of treating subkatabolic conditions by augmentation of radioactivity, independent of all the other possible causes of suboxidation, including acid conditions and oxygenation.

Another point of not insignificant importance is the perpetuation of the effect produced. It appeals to reason that the simple oxidation of the seat of tumefaction accomplishes practically nothing toward the restoration of normal oxidation of the general economy, and that to eliminate entirely the general elements of suboxidation, we must not only intensify the radioactivity of the whole body, but we must restore the natural oxidase elements, namely, phosphates and iodine, by internal administration. It is evident that the detritus laden vascular system must be cleared* and all of the essentials of active general oxidation must be restored in order to provide against the failure to oxidize the thrombi segregated from the original tumor, and against secondary "growth" in general.

At present it appears that the radiointensification of the whole body is best accomplished by the high-frequency currents of electricity, and administered with the use of the cage for "autoinduction."

In cases of general subkatabolism, is observed, in addition to local hyperplasias, a general gelatiniform condition of the tissues, as characterized by a general atony, and extension of the equilibrium length of muscular fiber, with consequent debility and weakness, softness and flabbiness of the muscles, more or less ptosis of the larger internal organs (especially in women), and often fibrosis and sclerosis of the vascular walls and of tissue stroma. The protoplasm, as superannuated in the tissues, and also stagnating in the vessels, as detritus, having thus acquired an increased affinity for oxygen, is largely consumed when the general oxidation is restored, and the body-weight is accordingly lowered. The reattainment of cell adulthood must be accomplished by the return to the normal protoplasmic proportions, and to its normal content of water, which was increased.

I have assumed without comment that the profession is already familiar with the mechanism of the production of subkatabolism by such agencies as fatigue, traumatism, pressure, irritation, etc., for it will be found described in most physiologies that fatigue, traumatism, and irritation are attended with the production of an excess of sarcolactic acid. Traumatism and pressure also will be recognized as factors of bruised and collapsed bloodvessels, thus retarding or arresting circulation in the part, and producing cell asphyxiation. In all these suboxidations so caused gelatiniform tissue changes are observed, however benign in character.

I have already¹²⁰ set forth the essential characteristics of malignancy of neoplasms, namely, the coexistence of living and growing cells with superannuated necrotic cells, in the growing edge. This condition may be due to prolonged continuance of the process and to the implication of cells of different katabolic digestibilities, interspersing each other, as occurs in the lips and other parts, where different tissues blend.

There is rapidly accumulating evidence that many apparently diverse states in the manifestation of disease are differences of degree only, and I know of no better illustration of it than the case of pain and anesthesia, as representing different degrees of tissue oxidation. For

example, suppose an Esmarch bandage is applied to the thigh, or a string to the finger. If we allow for some collateral but a greatly diminished blood-supply, we obtain more or less severe pain. Then if the circulation be entirely cut off complete anesthesia* is produced.

In malignant "growths" we observe tingling sensations, and in certain types of neoplasms great pain during the early period of their development, commonly followed by more or less anesthesia with the progress of the degeneration. I have directed attention¹²² to the fact that leprosy is characterized by anesthesia only in the advanced stage of its most degenerative form, and is not so associated with the tuberculous form. Many more illustrations of this could be given if space permitted. Pain is associated with hyperemia and inflammation, *i. e.*, reactive stages.

I am convinced, in those cases in which malignant tumors are cured by ligation of supplying vessels,⁶ by caustics, by liquid air, and similar treatments, that it is accomplished by virtue of their effect in producing universal sloughing, thus destroying the elements of malignancy, as described, namely, the living growing cells interspersing those already necrotic, of the "growing edge."

I assume that "pus" expresses the necrotic condition of liquefied tissue, or to express it differently, the liquefaction of necrosed tissue. Independent of putrefaction and sloughing processes, we observe that the ordinary emanations from our bodies, when liquefied by perspiration, especially in obese persons, quickly develop the characteristics of putridity. The microorganisms, which are the greatest producers of liquefaction, and at the same time cell necrosis, are also the greatest producers of putrefaction.

I have heretofore pointed out that no evidence is lacking to prove that the hyperplasia and degeneration of malignant states is due to cell necrosis from asphyxiation, followed by the superannuation of dead cells in the presence of the attendant stasis or arrest of oxidation, thereby producing so-called hyperplasia, in spite of more or less reduction of cell nutrition, which is directly with the circulatory stasis caused by the occlusion of the vessels, by tissue detritus. I have also accounted¹²³ for the liquefaction and final dissolution of involved cells, as parallel with the laboratory method of Kolliker, for the differentiation of the cell nuclei from the cell membrane. By this process we observe practically the same type of liquefaction and dissolution occurring as in subkatabolic states.

There are but two possible explanations of the so-called burns of excessive radioactivity, the effect of which is practically the same as caused by röntgen rays and radium, and of these, one involves the other: (1) Excessive fatigue of the cells, and degeneration from the sarcolactic acid, so-called; and (2) direct effects analogous to those of heat, which may primarily involve a transitory stage of cell fatigue. Both cause fibrosis, necrosis, and dissolution.

Ever since medicine evolved from the realms of occultism, and began to assume the dignity of a scientific pursuit, it has been observed that there exists a common factor pervading quite an extensive group of diseases, which by common consent have been recognized as diathetic diseases, and that by virtue of the influences of the several recognized etiologic factors of these diseases, singly and in combination, certain manifestations occur as definite effects thereof. Moreover, certain modifications occur in original processes, upon the interaction of new factors of this group, usually intensifying the same. The common factor of this group is subkatabolism, and its etiologic factors I affirm are those cooperating as before described.

An analysis of the nature of these suboxidation factors, their common pathogenic effects, their relations to

* See 120.

* See 174.

the so-called diathetic diseases, together with their pathology, is the ultimate object of my present labors. And it is my investigations to date that have led me to an appreciation of the value of the combined utilization of chemic biology, physiology and pathology, together with clinical pathology, as potent aids to the solution of these great problems.

Though space will not permit a thorough and extensive review of my method of analysis of disease processes, I may briefly state that I originally identify pathogenic findings by their fixed relations to certain etiologic factors of known nature. Following this I proceed to identify the same findings with other etiologic factors, and finally critically examine all the factors, so related, for common properties, which will individually or in combination, produce the tissue changes first studied. All this being accomplished, the study of the systemic distribution of disease becomes a much simpler matter.

It must not be inferred that I am representing this method as absolutely simple or free from possible errors. I have labored with it since 1894, yet I published my first paper on it only a year ago^{12b}, and already I find many instances in which statements should be modified or qualified, or both. My present progress is tediously slow, much slower than it would be if others were simultaneously working out a fair share of the problems involved.

The particular purpose of this paper is to plead for a rational therapeutics founded upon the idea of disease already set forth, thus negatively demonstrating the soundness of the hypothesis upon which the therapy is founded.

Some medical men have expressed themselves regarding my hypothesis of subkatabolic etiology of "diathetic" diseases as follows:

Your theory sounds well and plausible in the individual instances in which you have applied it, but to be a sound theory it must be compatible with all the diverse manifestations of what you assert are of subkatabolic origin, and moreover it must be capable of application in the explanation of the origin and manifestation of each and all of this group of diseases.

It has been further remarked:

I do not see how you can make it account for the origin of such diverse states as are expressed by pain on the one hand and anesthesia on the other, how one organ or group of organs is affected in one case, and at other times another, how in one case mental and nervous phenomena result, and are absent in the next, how inflammation and hyperpyrexia are in one case predominant and absent in another, how atrophy and hypertrophy can be due to the same cause, how so many and diverse primary etiologic factors can all be producers of the single result, namely, subkatabolism, etc.

On first thought an attempt to account for all of these problems by a single theory seems a paradox, if not an absurdity.

It is not surprising that as I have not as yet attempted to make a public exposition of this phase of the subject, and as this has been the stumbling block of all previous students of the subject, that many readers have been unable to grasp it in all its divers aspects. I regret that space will not permit a proper exposition of all the applications of the basic hypothesis, and as only an epitome can be here made, its fuller elaboration must await the completion of volumes now in preparation.

I do not wish to be misunderstood in regard to the precursor diseases of malignant tumors. I regard the present custom of attributing one disease as the cause of another, without qualification, to be one of the most misleading practices of our art. Even when etiologic relations are enumerated, they should always be duly qualified. The essential significance of the foregoing detailed diseases and conditions, is the recognition of the preexisting factors of subkatabolism and the exact nature of the direct cause, that it may be remedied, when possible. It is assumed that the professional reader is, for example, already aware that the suboxygenation element of hemorrhage is oligemia, that of anemia is oligocythemia,

that of chlorosis is hemoglobinemia, that of hyperacidities and oxidase deficiencies are stases or retardations of oxidation, etc., yet their order of occurrences, interrelations and interactivities, forming vicious cycles do not appear to be so well understood, and one object of this paper is the elucidation of these phases.

To facilitate my plan of presentation of this subject I would propose the division of subkatabolic etiology into no less than 4 stages:

1. The primary factors which produce the original effects upon previously or otherwise healthy persons, such as congenital deformities and defects, burns and other injuries, shock, fright, worry, anxiety, mental and physical overwork, strain, fatigue, and exhaustion (including sexual), chemic and mechanical irritation, vices of eating, drinking, smoking, and other vicious habits, cold, influences of sex, and the critical periods of life, poisons, bad air, sedentation, age, humidity, dampness of environment, lack of light and warmth, concussion, inequalities of otherwise normal influences, etc.

2. The immediate results of the primary factors, as suboxygenation, suboxidation, subalkalascence hyperacidities, poor blood (oligemia, oligocythemia, hemoglobinemia, etc.), poor circulation (cardiac and vascular) poor respiration (nasal, laryngeal, bronchial and pulmonary, etc.).

3. Diseases of the katabolic stases, susceptibility to infection, leukocytosis, tumefaction, degenerations, etc.

4. The vicious cycles of infections and the interaction of effect upon effect—progressive diseases.

The proofs that malignant growths are of subkatabolic origin and that they are subkatabolic conditions, are so abundant and apparent that, to me, it is absolutely astounding that so manifest a condition should have awaited the present day for the attainment of recognition. The fact that they are degenerative conditions has been fully understood for centuries, but the fact that cellular and tissue increase was also observed, seems to have caused all else to be forgotten, and thus abnormally augmented anabolism has been universally accepted as the pathognomonic factor, and a stasis of katabolism apparently has not been seriously considered.

After the attainment of growth and during health, a continuous mitotic division of the various tissue cells is compensating for others that are destroyed and eliminated, for, notwithstanding that every cell undergoing division is superseded by two cells, there is no quantitative increase of cells or tissues. In other words, we have a state of metabolic equilibrium. The destruction and elimination of the cast off cells is *katabolism*, and it is demonstrated by urea, uric acid, xanthins, ammonia, and other products in the urine. Only by the destruction of cells keeping pace with the rate of increase, by the mitosis, is the balance between anabolism and katabolism maintained. Should katabolism lag behind anabolism, tissue overgrowth would be the consequence.

I occasionally illustrate the mechanical theory of the process by assuming a hypothetical water-tank with an inlet and outlet capacity which are equal. This represents an equilibrium of metabolism. Then I have no trouble in convincing my hearer that the effect would be the same, namely, a rise of the water level in the tank, whether the incoming water is increased or the outgoing water diminished. The analogy is applicable to the increase of tissue volume as caused by a decrease of its destruction.

"But," says one, "how do we know, in the case of cancer, which it is? How do we know that it is a stasis of katabolism that causes the hyperplasia of neoplasms?" My reply is, that everything points to it. It is evident from every standpoint from which it may be viewed. Let us, for example, consider the irritation phase of it. It is well known that Virchow found this so common a cause of cancer that he made it the basis of his theory of its etiology. Any one, with almost any kind of scientific training, can easily satisfy himself from the abundant

literature of the subject: (1) That irritation produces the characteristic effects of subkatabolism, identically as produced by other causes known to produce such effects; and (2) conversely, without this element, namely, subkatabolism, in some form and from some of its known sources, tumefaction never occurs.

Now I assume that the profession is united on the universal physiologic doctrine that anabolism is largely a process of cellular nutrition, growth and division, while katabolism is one of digestion, which according to Croftan⁴, is a ferment digestion, typical of protoplasm, and of oxidation, both of which are dependent upon alkaline media. Moreover, I assume that it is universally established that alkalinity and oxidation are interdependent, for acidity we know will always increase with suboxidation, and oxidation will always diminish with the rise of acidity.

The investigator will invariably find that naked cells, wherever found, whether among the fundamental forms of animal life, which are unprotected from the vicissitudes of environmental irritations, as independent organisms, or as uncapsulated blood cells, as the leukocytes, are in a gelatiniform state; while the protected cells are able to and do attain the so-called adulthood, a condition which is as typical of protected cells as the gelatiniform state is typical of the unprotected cells.

We have seen that the several disease processes leading to the constitutional state of cancer, namely, suboxygenation (respiratory and cardiac deficiencies, circulatory obstruction, oligemia, oligocythemia and hemoglobinemia) and suboxidation (acidity and deficient and defective oxidases and incidentally a depression of the radioactivity of the cells) are without exception conditions also producing subkatabolism.

What physician has not observed that all exposed tissues, having suffered an abrasion, become gelatinified, and that the previously adult cells thus promptly revert to the rudimentary type? That it is not exclusively related to bacterial action is proved by the fact that the irritant may be a chemic one, which is essentially bactericidal in its nature.¹¹ Accordingly as the irritation is severe or long continued, the tissue degradation may be continued through the gelatiniform, colloid and fatty or putrid stages.

A significant fact which must not be ignored is that neoplasms are never examples of active anabolism, but conversely they are perfect exhibitions of stagnation and decay, just what would be the logical consequence of a superannuation of those asphyxiated cells which had failed of oxidation and digestive dissolution, after they had become disorganized, functionally impotent, and finally necrotic. Moreover, owing to infiltration of the vascular channels, supplying neoplastic areas, by cellular detritus, colloidal protoplasm, etc., thus occluding them completely against the supply of both nutrition and oxygen, we observe not only an arrest of further enlargement of the tumefaction, but a still more pronounced sluggishness and decay. In the so-called starvation treatment of malignant tumors, by ligation of supplying vessels,⁶ the chief difficulty experienced is the increasing proneness to sloughing, parallel with the decreasing anabolism so caused, the former effect owing to the incidental suboxidation. Except for more or less oxygenation supplied through anastomosing vessels, the method would be a complete failure, owing to the domination of dry gangrene and putrefaction, which ordinarily are somewhat in abeyance.

Not only are all of the etiologic processes of malignant growths those of subkatabolism, but all of those agents which have been found of any therapeutic value are manifestly supporters and intensifiers of katabolism, and it is as a plea for the intelligent adaptation of these several agents, as such, that I have been prompted to offer a contribution to this particular phase of the subject. The fundamental katabolic basis of the pathology of neoplasms also must be understood and recognized to

facilitate an adaptation of the necessary combination of therapeutic agents to each individual case; without it, chaos, empiricism, and inconstant results must be expected.

Individuals of both sexes not infrequently experience exacerbations of existing subkatabolic diseases as a direct result of sexual excesses, and if they are considerably lowered in katabolism, a single indulgence is often followed by more or less severe aggravation of the symptoms. Decline and obsolescence of sexual vitality of advancing years, is invariably connected with a parallel subkatabolism. Malignant neoplasms are invariably associated with a subkatabolism, developed prior to the nutritional decline, for after this we find the other evidences of subkatabolism, minus the elements of hyperplasia.

Hyperacidity, of gastrointestinal origin, by the neutralization of the alkaline mediums, necessary to both oxidation and tryptic digestion, constitutes another great retarding agent to katabolism, by thus directly antagonizing the process of oxidation, *per se*, and even in the presence of an abundance of oxygen and all of the other necessary elements of oxidation.

Failure of elimination of acids and other excretions, by the bowels, kidneys, and skin, may be responsible for hyperacidity and toxemia, by accumulation. As etiologic factors of progressive subkatabolic processes and vicious cycles, we must recognize accumulated acidity as a possible consequence of deficiencies of both oxidation and elimination.

Microorganisms, parasitic to the human subject, often do, by virtue of their irritations as foreign bodies, by the acid products evolved, or by the poison of their toxins, produce local or general subkatabolism, which may become a factor in the etiology of malignant growths; and yet no single or particular parasitic organism has been proved to be generally pathognomonic of the disease. We have good reason for believing that the so-called nonpathogenic fermentation organisms are much more largely responsible for subkatabolism than any other, though all resulting gelatinous and putrid tissues are extremely prone to secondary pathogenic bacterial infection.

Parasites unquestionably bear an etiologic relation to disease, yet I emphatically deny that the aggression occurs in the order and manner in which it is at present commonly described, namely, that the mere presence of any particular bacterium is sufficient to produce typical pathogenic effects in sound healthy tissue.

It is seldom, if ever, that a parasite which successfully invades an animal body, generates the necessary preliminary tissue conditions which render it a suitable medium for their life and multiplication, but conversely it may be stated, that such preinduced states are quite universally the result of so-called nonpathogenic bacteria (fermentation products) and other factors, mentioned elsewhere, of subkatabolism.

A fact of great interest and importance is that many find succor only in certain stages of subkatabolic degeneration, and after that particular stage is past they gradually decline and die out. This is especially well illustrated in the tubercle bacilli, and *B. lepræ*, which require for their sustenance and active propagation an intermediate grade of tissue degeneration, during which they thrive, and incidentally their activity is productive of local inflammatory reaction or general hyperpyrexia. After the passing of this stage, when a pronounced degenerative degradation is attained, during which the oxidation is nearly or entirely *nil*, even the parasite no longer survives.

The Fenwicks⁷, who are very acute observers, have found evidences of former tuberculous processes in 15.8% and Lebert in 14.7% of autopsies, after death from malignant tumors of the stomach, the bacilli having disappeared as well as the tuberculous processes. It is well known also, in the tuberculous form of leprosy,^{12d}

B. leprae diminish in inverse ratio to the development of the degenerative depravity, the logical operation and cooperation of the four stages of the subkatabolic etiologic factors. Living and active tubercle bacilli are never found in large abscess cavities any more than in healthy tissue.

During the height of the inflammatory stage of acute rheumatism, several observers have found joints infected with various parasitic organisms, yet conversely, Michaels and others have found them sterile. Probably the latter observations were made during a preinfection stage, or a later and a more putrid stage than the former.

In certain pulmonary diseases, bacteria are found which are more or less pathognomonic, yet when the tissues "break down" into abscess formation, the former parasites disappear and new ones take their places, or none may be found.

It is well known that in many infectious diseases an inflammatory course of approximately definite length is usual, the parasites dying at the wind-up, often poisoned by their own toxins, but probably often exterminated also by destruction of their media, or soil requirements.

It is of interest, in this relation, that chemic agents which combine to prevent the formation of water, as alcohol and the halogens, the latter by their affinity for hydrogen, and particularly bromin, not only intercept and prevent putrefaction, but also simultaneously act thus as antiseptics.

In condemning the universally exclusive use of radio-intensifying measures, let it be understood that I do recognize, however, that there occur, occasionally, cases in which at the time of treatment, the predisposing or acting causes of the subkatabolism have somehow been removed and the local malignant state of stagnant retrograde metamorphosis is the extent of the existing disease. It appeals to reason, in these cases, that radial intensifications, singly, are sufficient for the accomplishment of the necessary resumption of katabolic oxidation for the consumption of all the retrograde tissues and thus disposing of the essential conditions of the malignant state. But seldom, if ever, can that be done when the patient is markedly cachectic. Deficiencies of any of the vital factors of oxygenation and oxidation, other than of the radial activities of the tissue cells, which I admit are also essentially vital factors of oxidation, are not *per se* materially restored by radial intensification, used singly; and hence they must individually and collectively be remedied by separate measures. Oxygen or ozone inhalations, corrections of all respiratory defects, cardiac tonics, remedies for perverted distributions of the blood (cold saline baths, etc.) circulatory obstructions, poverty of the blood (iron, potassium iodid, etc.) administration of internal oxidants (cod-liver oil, etc.) and oxidase elements (phosphorus, potassium iodid) and tissue contracting and inspissating agents as ergot and adrenal extracts, may be indicated. The value of the recently advocated use of quinin as an aid to the tissue response to imparted radioactivity, by virtue of its property of fluorescence, future demonstration must determine. It is very significant in this respect that some of the older writers were loud in their praise of Peruvian or cinchona bark, of which quinin is a derivative. This is especially mentioned by Cooke³ (Co. tinct. Bark, B. P.).

It is exceedingly interesting to review the literature of cancer therapy and to observe the empiric employment of phosphates, phosphorus, iodine, potassium iodid, alkalies, iron, cod-liver oil, hydrochloric acid, "tincture of bark," etc., and the diverse reports of success and failure obtained by different observers, and by the same observer in different cases. Cod-liver oil, however, has always been the universal favorite, as they blindly used all these remedies as a routine treatment.

Gastric and intestinal fermentation, as a cause of sub-oxidation by virtue of its resulting hyperacidity, is a factor of importance. This class of cases evidently was

benefited by the old-time practitioners, by hydrochloric acid and alkalies. It is of interest in this connection that Osler and McCrae,⁹ confirming the observation of Golding Bird, made as early as 1842, of v. den Velden, in 1879, and a host of later observers, including Riegel, Ewald, Huebner, Honigmann, Thiersch, Jaworski, Gluczynski, Kahn, v. Mering, and Rosenbach, found this element quite universally absent in gastric cancer, thus predisposing to fermentation and putrefaction.

As may be inferred, I am not an advocate of the extensive operative measures proposed by Paget, and, moreover, I do not favor any procedure which involves an incision into the "growing edge" of neoplasms. I do, however, favor the evacuation of pus and the cleansing and oxidative purification (hydrogen dioxide, etc.), of purulent foci in all cases, and in the complete extirpation of such neoplastic internal organs not essential to life, as are not amenable to radiotherapy. I object to surgical operations as preliminaries to radiotherapy, except as mentioned. I am convinced that recurrence is often due to excising slices or curetting from the growing edge for microscopic purposes, thus setting free thrombi, which grow even after the removal of the original neoplasm. As much as I value the statistics of cancer, derived from such microscopic examinations, I would seriously object to the disruption of the growing edge in the tumor of anyone dear to me, even for such purposes. I prefer the better chances of a cure, than the satisfaction of the knowledge thus gained.

The inconsistent results obtained, the too frequent admixture of failures combined with the successes, and the frequency of recurrences, coupled with the extravagant claims of many writers in the medical journals, and more especially of that class that seeks notoriety through the lay newspapers, have so disgusted the conservative members of the profession that already an unfortunate reaction is taking place against radiotherapy. I not infrequently hear it denounced as a commercial project, devoid of intrinsic merit. I have just learned that one very eminent dermatologist of this city who has been for some time administering the several types of radial therapy, has recently abandoned them for the actual cautery and other of the older remedial measures. It is needless to say that he, of course, administered his radiation measures singly in the same way that he applies the cautery, namely, independently.

It is evident that the profession is confronted with the choice of either placing the radial therapeutics of malignant neoplasms upon a more stable scientific basis, or allowing it to suffer a more universal lowering in the estimation of the good men of the profession, and finally to be abandoned to the quacks and charlatans, who will thus inherit a more potent therapeutic weapon than would be then possessed by the ethical profession or could possibly be replaced from any other source.

It is a logical sequence that instead of independent radial therapy, to insure successful issues, we must combat with equally effective measures all factors of suboxidation, and not infrequently two or more as coincidentally involved. For example, in some senile cases it is necessary to rehabilitate the cardiac function, give iron for anemia, and oxidases (phosphates) and alkalies as antacids, in a single case. It is well enough to use agents singly for experimental purposes, but for therapeutic achievements it is often a fatal error. Moreover, in probably the majority of cases, the best results may be obtained by a general intensification of the tissue activities of the body, which are frequently more or less stagnating in subkatabolic depravity.

Another point of importance in the treatment of hyperplastic and other subkatabolic conditions, is the necessity of a word of caution to radiographers carefully to avoid a too intense radiation of circumscribed areas of tissue, because of the fibrosis or sclerosis which is inevitably the consequence of a too active oxidation, whether

produced by radioactivities, Coley's toxins,² or certain microorganisms. I have pointed out in a previous paper^{12b} that the unfortunate defect in the treatment by the organisms and toxins of erysipelas and prodigiousus, so brilliantly worked out and introduced in this country by Dr. Coley,² and which at one time seemed to promise so much, was the cicatricial formation, often occurring before the retrograde tissues were oxidated away, with the result that they would inversely become less susceptible to radiation or stimulative oxidizable influences, until finally they entirely failed to respond to further attempts in this direction, the neoplastic process thus becoming an incurable one. It is a chemiophysiology fact that all tissues, as they undergo gelatification, liquefaction and putrid or fatty degeneration, become correspondingly more and more oxidizable; in fact, as they are deprived of oxygen for an increasingly greater length of time, they acquire a correspondingly greater affinity for oxygen, and when suddenly measures are taken which supply previously absent factors of oxidation, it may become excessive, and be expressed by inflammatory cicatricial formation. In another paper,^{12d} I advanced this analysis as the explanation of Chapin's results with those toxins in leprosy;¹ the same may be applied to the defects obtained in the cases in which arsenic and other oxidants are intrajected in neoplastic tissues. It is desirable to promote oxidation, a degree short of active inflammation, and maintain it as constantly as possible until the oxidizable (superannuated) cells which are responsible for the hyperplasia, are oxidated away.

A cause of failure, of no mean importance, is the defect which arises from the incompatibility of the therapeutic demands in many cases, with those of a remunerative office treatment. As is well known, röntgen ray and high-frequency current equipments are both expensive and cumbersome; those of greatest efficiency being most so. Thus to make such treatments pay, the physician must contrive to administer on alternate days a very intense radioactivity of short duration, to the involved tissues, in order to accommodate the patient's pocket book and permit of the treatment of quite a number of patients during the day. Such a procedure will be effective in a certain reduced percentage of cases, but there is also a large number which does not do well under such a regime. The fact of the matter is that metabolism is a constant, not a periodic process, and a logical plan of augmentation or intensification of the cellular radial activity would be one more prolonged, less intense, and of more frequent administration. As I have pointed out, in the use of Coley's toxins, often inflammatory fibrosis is developed before the patient is cured, and that so invariably interferes with the further augmentation of the necessary active hyperemia, that as a result, the therapeutic progress comes to a permanent standstill. That being exactly what happens when such intense radiations of short duration are periodically applied as produce hyperemias of 2 or 3 days' duration, progress ceases with the attainment of a certain degree of circumscribed fibrosis, and to this occurrence often the efficiency of the method is discredited. It is *prima facie* evident that to perfect this treatment a more evenly balanced administration must be resorted to, even if it must be abandoned to the hospitals and sanatoriums, where facilities may be adequate for its proper and successful application.

The limitations of my present space oblige me to refer the reader to my monograph of a year ago,^{12b} which, though in need of revision and elaboration now, still will be found of great value as a treatment basis and as a collaboration of the present paper.

We have seen that oxygenation and oxidation may be compromised by many factors and that there are many conditions and manifestations to search for, both in the case history and in the condition presented. The treatment of anemia, chlorosis, etc., I will not include, but simply urge the importance of it, when indicated.

The same of syphilis and other antecedent diseases mentioned. Success in therapy will not attend their neglect.

In conclusion, it is incumbent upon me to acknowledge the general therapy of malignant growths of some medical men of New York, who have come to my notice. Dr. H. G. Piffard informs me that long before the publication of my writings on malignant tumors, he has been convinced of their subkatabolic origin, and has treated such patients along these lines. Dr. Charles W. Allen has also long recognized the multiple sources of origin of hyperplastic processes and has always advocated the combined as distinguished from the single (radiation) therapy. Dr. G. Lenox Curtis,⁵ also, has certainly met the subject of subkatabolism quite squarely in his advocated treatment by what he styles "electric ozonation," under which he includes the "combined influence of electricity, light, heat and ozone." With this, he states, he combines iron and other remedies, as indicated in different cases. There are, undoubtedly, other men who are conducting a general rational therapy of subkatabolic conditions as indicated by the nature of the process and the antecedent and complicating diseases, who have not come to my notice or perhaps have not been reported in medical literature.

As far as my observations go, those therapeutists who have compassed and treated the several diathetic relations together, with the radiotherapy, have obtained results that for constancy have not been attained by those treating exclusively with the latter.

PERSONAL OBSERVATIONS ON THE ADVANTAGES OF CERTAIN ARCTIC LOCALITIES IN THE TREATMENT OF TUBERCULOSIS.

BY

FREDERICK SOHON, M.D.,
of Washington, D. C.

In any plan of treatment of tuberculosis we must consider the causes which induce the disease, and the factors which prevent infection and which so often lead to a cure by nature alone. These factors must be the foundation of treatment.

We cannot class as one of these factors the hope that the body has a developed special material to repel or cure attacks of tuberculosis, as is the case in many of the contagious diseases. No one exposed to tuberculosis without contracting it is definitely immune—given a protracted state of lowered vitality, local conditions for infection, the presence of the infective agent, and the results are sure. There has been little chance to develop a special immunity or effective antitoxin, as the toxin

produced by the tubercle bacillus is slight and the mortality has been high. Consequently a tendency to a protective or curative antitoxin has, at best, but hardly begun in the whole race, and we cannot expect such to be perfected in the individual.

We must look for the cause of immunity and recovery to the fact that each tissue cell, like every other unit of life, has an inherent tendency toward stability and a capacity for self-protection when properly innervated and nourished. That the vital resistance of the cells is so often successful against the lodgment or growth of the tubercle bacillus is favored by the fact that the germ does not generally possess virulent attacking and conquering powers. Like all germs, it has varying degrees of activity, from its attenuation in scrofula to its malignancy in acute tuberculosis; but in general it cannot be considered aggressive, for, though it claims its 1 death in 7, it has its victims offered to it. The vigorous will not contract pulmonary tuberculosis, while those of low vitality can hardly avoid it. The vital resistance of the cells is the safeguard both against primary tuberculous infection or the extension of such infection, and good general health insures this resistance, preserves it, and restores it when damaged.

When the stability of the cells is undermined and the bacilli gain lodgment, the body still has protection against the germ and the damage it does, through conservative pathological changes. The inflammatory zone, the throwing off of cells, the phagocytosis, the formation of the fibroid tubercle, etc., are conservative efforts of the economy to protect itself by ridding itself of, or isolating, the weaker units which have succumbed; and this defense would be successful if the disease were limited to the tuberculous infection. This is illustrated in patients with extensive uncomplicated tuberculosis who live to old age with a "fibroid" lung, and retain considerable bodily vigor.

But tuberculosis, in most cases, is not limited to the inroads of one kind of bacilli; it is a mixed disease, the chief symptoms of which, and danger to life, are caused less by the tuberculous than by the pyogenic infection. When the disease has obtained a hold, the catarrhal condition, the direct irritation from dust, the pus germs, and every variety of air-borne life which settles and develops, are powerful reinforcements to the tubercle bacillus, which alone, both by its presence and its slight systemic poisoning, would be comparatively harmless. As a result of the multiple infection the whole economy becomes disorganized. It is poisoned by the various ptomaines and the attendant formation of products of inflammation and cell deterioration, and directly irritated day and night by impulses from the infected area which involve the whole sympathetic system and thereby waste vital strength. No organ can do its work properly, the body is enervated and poorly nourished, and the consequent further impairment of health reacts on the tissues exposed to the infecting agents and encourages further development of the disease. Therefore it is not enough to fortify the body by building up the health under adverse conditions, but we must have such environments that the body will be relieved of the handicap of concomitant infection.

The good obtained through better hygienic conditions has encouraged in turn the sending of patients to high altitudes, the climatic treatment, the cottage sanatorium idea, etc., and the constantly growing appreciation of hygiene, as holding the most important aids to a cure, has lately served to bring prominently forward what is called the open-air treatment. That an out-door life is beneficial to the tuberculous is proved by the results in sanatoriums which report about 50% as cured, and 25% as improved. These results are so far beyond what it was thought possible to obtain not many years ago that enthusiasm is perhaps swinging the pendulum of hope too far, and bitter disappointment will follow. This method of treatment has been much exploited of

late by the press as something entirely new, and unfortunately in such a manner as to convey the idea that only "fresh air" is needed. Fresh air, in its popular signification of more or better oxygen, is by no means the main item in the open-air treatment, and a random search for air alone will do no positive good. The tuberculous will not get well just because they go out of doors, but they must live that life as a treatment which uses certain conditions in a proper way to encompass a definite object. They must seek these conditions and live in a manner to profit in full by them. Give nature a fighting chance against the tubercle bacillus *alone* and she will win; this is the proper fundamental idea of the open-air treatment.

Among factors for a cure which may be obtained by sending patients out of doors, I place first, the direct influence of the sun's rays, and mark, I do not say sunlight. In the full stream of vibrations that flow from the sun the light-rays are but one item. Though light itself has a direct influence on metabolism recent research shows that rays with which we do not become acquainted through sensations of light or heat have an even greater effect. Many of these rays are deterred by glass and are not reflected by walls. Therefore the tuberculous should seek not only light, which can be had within as well as without doors, but should take the sun's rays direct in their entirety.

The second advantage, perhaps coequal with the first, is that one may, by a proper out-door life, lessen the liability to pus infection and irritation by dust in the diseased area. The house air contains, in addition to the inorganic particles, much organic matter that will decay and become poisonous when inhaled, and also dangerous microbial life that finds conditions for development within walls. These are the agents that change many simple and mild cases of tuberculosis into the dangerous type. Out-door conditions are better as sunlight is a germicide. Undoubtedly much of the benefit obtained in winter at open-air sanatoriums, when the earth is covered with snow, can be ascribed to the fact that the snow lessens the amount of dust and harmful bacteria in the air. Third, a proper out-door life instills into the tuberculous patient a feeling of freshness instead of languor, and the favorable reaction of his feelings on his own physical condition is not unimportant.

In attempting to secure these advantages time is important; not only should treatment begin early, but results should be gained in the shortest possible time by the patient being at a place where the best conditions are obtainable. This disease will continue its local inroads until that condition of health is regained in which no further germ encroachment is possible. It is evident that the more time consumed by half-way measures the more there is to cure, and it is also evident that the good obtained under only fair conditions will have to work against a constant drawback of new infection.

For the ideal open-air treatment, we should place the patient in surroundings where the inroads of the tubercle bacilli are not assisted by their allies, if at the same time such surroundings are conducive to rapid increase of bodily vigor, the cure will be won if there is any chance left for nature to effect a cure. Such surroundings can be obtained almost in perfection during the summer months in some of the northern fjords of Greenland.

As most are only acquainted with these regions through tales of adventure and suffering allow me to introduce the subject by comparison with what tuberculous sufferers often endure in our country for an open-air cure. There, one need not bear in summer a zero temperature, the privations of the backwoods, the dust of an alkali desert, the enervating influences of arid regions, or scorch by day and shiver by night as in the mountains. One need not violate a single rule for the preservation of, or obtaining good health. Privations

and suffering have ever been in the far North, because a certain thing was to be done, and done at a certain time, and under such conditions that food, comfort, health and everything else had to be subservient to the main end of exploration. However, these regions are now known, and if the main business is the regaining of health everything can be nicely adapted to that end.

The fogs, cold winds, rain, and snow which may occur even in summer in Arctic regions are confined to the sea and coast. In the protected fjords some miles from the coast the conditions are entirely different, and in what follows I refer to the protected inland bays.

The general appearance of the Greenland fjords is a stretch of rocks and cliffs from which the snow has melted, mountains from which the icecaps never melt, glaciers coming down to the sea from the inland ice, open water and icebergs. It seems at first a dreary, desolate waste; but it is not cheerless. Nature there shows a primitive grandeur, and life in summer is not monotonous. There is a combination of the scenery of canyons and alpine peaks. A wealth of color is over all in the strata of rock, in the varied hues of lichen and moss, in the blue and pink tints of the icebergs, and, during the usual night hours when the sun is in the North, sunset and dawn effects of glittering gold and silver and flaming crimson that reflect the color on water and ice. Those interested in the sciences can find there virgin ground for investigation. Those who take pleasure in hunting can find walrus, deer and duck. The keen zest of life in the Arctic and its fascination is best condensed in the familiar expression, "arctic fever," this inoculates everyone who once beholds the beauties of the North and from their charms no one ever fully recovers.

Sunshine, the most beneficial factor in the cure of tuberculosis, is there as it is nowhere else. The sun never sets, and though its declination is low, its rays are intense from the clearness of the atmosphere and the repeated reflection in all directions from water and ice. Tanning of the skin always occurs, and sunburn is not uncommon. Sunburn is not caused by visual light rays, but by rays beyond the violet. It seems that some of the ultraviolet rays are stronger in the North, and that the actinic rays at least are stronger is shown by every photographic exposure. As some of these ultraviolet rays have the most influence on the vital processes there is there a light not only constant, but also more potent. Perhaps such an increase of energy-imparting waves is a compensation to life in a region otherwise ill-favored. There, plants spring from seed to flower in a few weeks, animals are large and vigorous under unfavorable conditions of food, and there is a feeling of buoyancy and vigor given to man in an Arctic summer as can be duplicated nowhere else. Perhaps the increase of energy may be due to other unknown factors—the different terrestrial and atmospheric electric conditions, ozone, etc.—but whatever the cause, the prompt increase in health and energy is apparent.

The following data are compiled from the diaries of my two voyages with Commander Peary, and the logs of 3 of his other expeditions, and includes days between July 28 and September 6, spent between 69° and 78° N. In all the days taken together, the sky was clear in 67% and the remaining 33% included all other conditions, such as overcast, slightly hazy, rain or snow. Selecting from the foregoing the days spent in fjords some miles from the sea there was clear bright sunshine in 88%; that is, the sun showed each hour of the 24 in practically 9 days out of 10.

General weather conditions in fjords: Days entered as splendid or perfect 43, good 2, disagreeable 3, bad 1. That is, in 49 days there were only 4 in which one would not desire to be out and about. From August 18 to 27, 1892, the Windward was at anchor in the same place and the following temperatures were recorded on the deck of the ship. Average minimum 37.9°; average maximum 48.9°; least variation in 24

hours 5°; greatest 20°; average 10.9°. At this time the sun had begun to set, but in July and the first half of August the temperature often fluctuates only 1° or 2° in a day. In connection with these figures it is noteworthy that though the air is cool, the rocks under foot are warm from the constant sunshine, and that the cold is not at all uncomfortable except when the wind blows. As figures cannot convey a proper idea of weather conditions I may illustrate further by saying that if we took one of the few bright, bracing days of the past winter here and imagined it protracted practically unchanged hour after hour for a month we would get a fair idea of the weather in some of the Greenland fjords.

The atmosphere is so absolutely clear that one is unable to judge correctly the distance of even nearby objects. I may emphasize this by illustrations which are not deceptive even if the eyesight was. One may walk toward a point apparently but a mile away, and walk for an hour without seeming to get nearer to it or even very far from the starting point. One may try to throw at a mark apparently within easy range, only to find that the strongest throw will cover but half the distance. *There is no dust or other harmful atmospheric contamination.* There is no dirt; the rocks are clean and every bit of dead lichen or moss that is not carried away by the melting snow in spring is greedily held fast by the living roots.

On the Peary expedition of 1902 I exposed dishes of agar and introduced into culture tubes pebbles, bits of vegetation and water. Only this culture medium could be used and the tests were limited to out-door conditions but included the air, ground and pool water at Commander Peary's winter quarters. Of 6 dishes exposed from ½ to 2 hours 2 were sterile and 4 gathered only a common white mould (*P. glaucum*). Only the hay bacillus was obtained from pebbles. Water yielded the hay bacillus, *Bacillus liquefaciens fluorescens* and an unclassified nonpathogenic saprophytic rod organism. The tests of the cultures were kindly made for me by the officers connected with the Marine-Hospital Service Laboratory. Many of the tubes had dried and perhaps other organisms may have been present and died. The absence of pus or other pathogenic germs is what would be expected as these cannot live in direct sunlight or develop in an unceasing low temperature.

Disease is never endemic among the North Greenland Esquimos. In winter their environments are changed from the natural, for then they hibernate in the heat and filth of their igloos, and as a result in some years they are visited by epidemics of contagious diseases which reach them air borne, or by ships, or through the migrations of game or birds. These diseases are not native, for they never reappear the following winter. When summer comes the Esquimo leaves the warmth and accumulated filth of his igloo and lives a primitive open-air life in tents, the summer sun disinfects the region and he is always well.

Though these regions are practically germless, one going there would carry a varied assortment of pathogenic germs along. The virulency of a contagion depends on its constant transmission from host to host, and though one's mouth may be (bacteriologically) a culture ground for pneumococci, staphylococci, and streptococci, they are attenuated and will do no harm, even if he is exposed to depressing conditions that at home would make him liable to illness. Every Arctic explorer has remarked on the absence of ill health. Pneumonia is unknown and one does not "take cold" from the worst kind of exposure. The importance of this is readily seen when we reflect that the susceptibility of the tuberculous to a succession of colds at home often of itself prevents a cure.

To illustrate the general conditions favorable to health (and the regaining of it) I cite the following: Meat never spoils when exposed to the air; if kept away from the direct sunlight it may become coated with

mold, but it will not rot. Nothing decays there; the dejections lose their offensiveness, and even dead bodies do not seem to putrefy—apparently they simply disintegrate and disappear under the influences of the elements. I was astonished, when at Cape Sabine with Commander Peary, to see the condition of the clothing, skins and furs in the former camp of General Greely. Organic matter had lain exposed here for 13 years and was still in an almost incredible state of preservation.

Good wholesome food is possible in the Arctic, as elsewhere in these days of cold storage, and as great a variety as can be had on an ocean liner can be had in the North. Fresh meat from caribou, seal and hares is obtainable, and ducks and auks are there in thousands.

The Arctic induces a prodigious appetite, and the taste runs naturally to the kind of food the sufferer from tuberculosis needs, which we wish to give him at home but which he has no appetite for and cannot assimilate. In the North man craves meat, and particularly fat meat. The Esquimos are so full-blooded, from their exclusively flesh and blubber food, that violent exertion always makes them bleed from the nose, and they also bleed from excitement, grief, or laughter. The invariable and extraordinary increase in weight of a crew in the north, subsisting on salt pork, corned beef, potatoes, and bread, shows what can be done for tuberculous patients if the climatic incentive to food is combined with a proper regimen. On both occasions in which I have been to Greenland I have exceeded my usual maximum weight, gaining the first time 30 pounds in 2 months, and the second time 19 pounds in 6 weeks.

These regions of perpetual sunshine can be reached within 10 days from Nova Scotia, or less than 3 weeks from New York, and the trip can be made in safety and comfort in a suitable vessel converted and appointed for the purpose. Fogs along Newfoundland and Labrador will be inevitable, and bad weather as luck brings it; these are the usual chances of an ocean trip. As a safeguard against possible severe storms, unusual there in summer, the vessel is never beyond reach of a sheltered harbor that can be made on a falling barometer. The sea is usually smooth, and is always so when there is any drifting ice.

To anyone who has ever indulged in athletic sports or enjoyed a simple fishing trip the fjords of Greenland will give a most enjoyable summer vacation. Those who are "run down" from business cares can there find a complete change amid environments that compel a rapid restoration of nerve tone. Parties of the tuberculous can live there in summer in all comfort, either in tents, in quarters, or aboard ship. They would forego luxuries but none of the necessities of a simple hygienic life, and though they would miss as many familiar conveniences of a home life as they would anywhere else away from home, they would be repaid in the better health acquired. The cost would not be excessive, or higher in the end than at many popular health resorts.

The time is short in which it would be advisable for tuberculous patients to be in the Arctic, and the question naturally arises as to whether 3 months of even such ideal conditions as are found there can be effective toward a cure. The contention is that nature has a means of curing, and does cure, tuberculosis, if she is not handicapped by the mixed infection. How long it will take to reach the necessary standard of vital resistance depends on how the patient can be forced along the upward path.

In the Arctic this forcing takes place naturally. The step is radical; the patient is removed entirely from all foreign influences which favor a further development of the disease or which militate against an improvement, and is placed at once under influences conducive to vigorous health. Three months under such conditions may be time enough for a cure in patients not greatly run down, and the time is at least ample to give the patient a good start on the upward path. In this con-

nection we may reflect on what is accomplished in a half year, or less, in places not so favored.

To recapitulate: Constant sunshine, which brings health and energy. A germless and dustless air that gives neither irritation nor extra infection. An unvarying and bracing temperature that invites out-door life and exercise. A climate that creates an appetite and a life that brings the ability to digest and assimilate. A life of new recreations that banish loneliness, and of enticing interests so different from the ordinary that absolute nerve rest is secured. A country in which colds and catarrhal conditions are not found, and even the healthy invariably improve in well-being. All of these advantages, except the perpetual sunshine and the germless air, can be obtained elsewhere, but here they are furnished altogether and each in perfection. They are also furnished at that time of the year when conditions are most unfavorable elsewhere.

The world in general, which wonders at the utility of Polar exploration, will some day be indebted to those who have endured hardships and given life to work in the Arctic. Much credit is due Commander Peary for his continuous and persevering efforts not only to extend geographical knowledge, but to make these northern regions accessible and known to all branches of science. Many institutions of learning and scientific bodies are richer through his expeditions, and he has opened up a territory that is now easily reached and has unequalled conditions for the cure of tuberculosis. I was impressed by this fact on my first voyage with him in 1896, and in 1902 I went North again to reconsider it on the spot. This investigation but served to strengthen my opinion that in summer these regions are entirely suitable for, and beneficial to, the tuberculous, and that the unequalled natural advantages for a cure can be practically utilized.

AN INVESTIGATION OF CERTAIN OF THE REFLEXES AND SENSORY PHENOMENA AND THE CONDITION OF THE EYE-GROUNDS, BASED ON A STUDY OF 103 HEALTHY YOUNG MEN. KNEE-JERKS, ACHILLES-JERKS, CONJUNCTIVAL AND PHARYNGEAL REFLEXES, PUPILLARY REFLEXES, STEREOGNOSTIC APPRECIATION, MUSCULAR AND SPACING SENSES.*

BY

THEODORE DILLER, M.D.,

of Pittsburg, Pa.

Neurologist to the Allegheny General Hospital; Visiting Physician to the Insane Department, St. Francis Hospital.

The 103 persons, the study of whom forms the basis of this communication, were male students, whose ages ranged from 18 to 33 years, the average being 22½. For various reasons, into which I need not enter, every single one of the subjects of inquiry was examined into a less number of times than would correspond with the total number of persons examined—103.

In the briefest tabular form the results of the investigation are here noted. The phenomena investigated are among those commonly inquired into by the neurologist.

AGES.

Youngest	18 years
Oldest	33 "
Average age	22½ "

KNEE JERKS.

Quick and prompt excursion	36
Slow and long excursion	11
Slow and short excursion	31
Difficult to elicit	21
Absent	0

Total number of tests 99

* A paper read before the Pennsylvania State Medical Society at its meeting held in York, September 22 to 24, 1903.

ACHILLES-JERKS.

Prompt	28
Slow	7
Absent	0
Number of tests made	35

Conjunctival Reflex.

Present	6
Absent or faint	6
Sluggish	1

Number of tests 13

Pharyngeal Reflex.—This reflex was tested in quite a number of cases, but no exact results were set down, partly because of the difficulty of so doing. But I can say, in brief, that the reflex was sluggish or absent in about half the subjects tested.

Reflexes of the Irides.

Tests made on dark days	70
Tests made on bright days	29

Total of tests 99

Average size of pupils in the light, with subjects near to and directly facing the window 2.76 mm.

Average range of excursion of the pupil in the light reflex 1.39 mm.

The range of excursion of the pupil was 0.5 to 1 mm. in 43	Cases.
The range of excursion of the pupil was 1 to 1.5 mm. in 30	
The range of excursion of the pupil was 1.5 to 2 mm. in 18	
The range of excursion of the pupil was 2 to 2.5 mm. in 4	
The range of excursion of the pupil was 2.5 to 3 mm. in 3	
The range of excursion of the pupil was over 3 mm. in 0	

Total number of tests 98

Pupillary Reflex in Accommodation.—Excursion of pupillary contraction in accommodation.

Number of tests made	31
Average excursion	0.967 mm.

The pupillary excursion in accommodation was in all tested in 94 subjects. It was found recorded as:

Absent	3 times
Sluggish or slight in range	24 times
Prompt	67 times
Total	94

Pupillary Equality.—No marked differences in size of the pupils were noted.

Convergence.

Normal	17
Defective	18
Absent	1

Total 36

The convergence test was made roughly by directing the subject to look at a distant object and then at the finger held a few inches from his eyes.

Eye-grounds.

Number of cases in which cupping of the optic nerve appeared more or less marked, and in which distant gray stippling could be seen at bottom of the cup	13
General optic atrophy	0

Number of examinations 99

The stereognostic appreciation, muscular and spacing senses were tested in a considerable number of subjects. Here but slight individual variations were noted.

So much for the exact figures so far as I have been able to give them. Let me now discuss briefly the different subjects of inquiry chiefly as revealed by the figures given.

Knee-jerk.—While in no case was this phenomenon absent, yet in 21, or over a fifth of the subjects tested, it was more or less difficult to elicit. In several of these cases repeated blows were required to bring out the jerk, and without the aid of the percussion hammer the jerk would have been recorded as absent. In a few of the "difficult" cases the jerk was, when finally elicited, quite prompt. The conformation about the knee-joint, the size and position of the patella tendon all varied greatly. The knee-jerk varied greatly both in length and rapidity of its excursion. It would be desirable to measure definitely, and record both these elements.

Achilles-jerk.—Here in a fifth of the 35 subjects examined, the jerk was more or less sluggish, but in no instance absent; whereas in over half the subjects the knee-jerks were more or less sluggish or else difficult to elicit. The position of the achilles tendon was much more constant than the patella tendon. In brief, the achilles-jerk is more constant than the knee-jerk, and is elicited with less difficulty.

This observation is quite in accord with those of other recent investigators who have written on the subject. Bramwell,¹ after very extensive observations, says that the achilles-jerk is constantly present in persons in health under 50 years of age.

In diseased conditions he found it absent when the knee-jerk was absent (tabes, multiple neuritis, etc.), and he further states that in tabes it is usually lost before the knee-jerk. Babinski² had recently pointed out that the achilles-jerk is usually lost in the affected side in sciatica and constitutes a differential diagnostic criterion when the question of hysteria arises. Sarbo³ found the achilles-jerk constantly present in 300 healthy persons he examined. He examined 92 tabetics, and found both knee-jerks absent in 79% of the cases, while both achilles-jerks failed in 88% of the cases. He, too, found that the achilles-jerk disappears before the knee-jerk in tabes. Walton and Paul⁴ tested the achilles-jerk in 500 healthy persons, whose ages ranged from 5 to 82 years, and failed to elicit it in only one instance. In 13 of these persons the knee-jerk was feeble, and only elicited with the aid of reinforcement and after repeated blows; while in all of their subjects the achilles-jerk was elicited with ease.

Thus it will be seen that the results of my own investigation of the achilles-jerk in health are quite in accord with those of the more extensive investigations I have just cited. Moreover, the investigators quoted unite in considering the presence or absence of the achilles-jerk in disease as of greater significance than the presence or absence of the knee-jerk. The achilles-jerk must, therefore, be considered of great importance, and should always be tested along with the knee-jerk. It is probably best elicited by striking the tendon with a rubber hammer about 2 inches above the os calcis, while the subject is kneeling on a chair with his face to and while his hands are grasping the back of the chair.

In view of the evident constancy and importance of the achilles-jerk, it seems strange that it should have been neglected until within the last few years. For example, such an acute observer as Oppenheim, in his "Lehrbuch," published in 1898, speaks of it as an inconsistent phenomenon, while in the "Traité des Malades de la Moelle Épinrière," by Déjerine and Thomas, published only last year, no mention is made of it. Starr, in his work on organic nervous diseases, just from the press, places little emphasis on it.

Conjunctival and Pharyngeal Reflexes.—Since their absence has been considered by some as stigmata of hysteria, the fact that in fully half of the healthy men tested, they were sluggish, faint, or absent, carries with it its own commentary. The number of tests made by me, however, was small.

The Irides.—Here the great difference in the size of the pupils and of their range of dilation and contraction to shade and light, is of interest. In tabetics we often note instead of the complete Argyll-Robertson pupil, an incomplete one when, *e. g.*, there is a slight reaction to light of 0.1 mm., 0.2 mm., or 0.3 mm. In several of the subjects investigated, the range of pupillary contraction was a scant 0.5 mm. Thus it will be seen that in the 99 persons examined, the range of pupillary contraction to light was very great, approaching the incomplete Argyll-Robertson pupil on the one hand, and being so extensive as 3 mm. on the other hand, the average range being 1.39 mm.

Pupillary Excursion in Accommodation (0.967 mm.), was, roughly speaking, about two-thirds as extensive as

that for the light reflex, and failed entirely in 3 cases, while in 24 others it was comparatively slight in range.

The range of the pupillary excursion was measured by holding aside the eyes a small strip of card-board, having on it black circular marks ranging from 1.5 mm. to 8 mm., as recommended by Haab. This plan of recording pupillary excursions is one which I believe may be commended as tending to greater accuracy in records. It is extremely simple, and requires but little time.

Besides the great variation in the range of pupillary contraction to light and accommodation, great differences in the rapidity of the iridic movement was also noticed. This, unfortunately, cannot be expressed in figures.

Convergence, it is to be noted, was defective in slightly more than half the cases tested, and entirely absent in one instance.

The eye-grounds were especially examined with reference to one point, viz., the presence of gray atrophy or appearances suggestive of an approach to this condition. While in no instance was the diagnosis of gray atrophy made, yet in 13 eye-grounds more or less deep and extensive cupping with gray stippling at the bottom was discovered (slight degrees of cupping are not included). In 2 or 3 instances these appearances were so pronounced as to resemble strongly those seen in parietic dementia, where unmistakable gray atrophy subsequently develops. In short, these fundi phenomena would have been by me considered as very significant, had they been associated with symptoms pointing to tabes, parietic dementia, or disseminated sclerosis.

Equality of the Pupils.—In a few instances slight inequalities of the pupils were noted, but in no case was this inequality conspicuous.

Thus it will be seen that the ocular phenomena investigated vary greatly; and the lesson their study very forcibly teaches is that we ought to be very cautious in drawing conclusions from the variation of these phenomena, especially when unsupported by other signs or symptoms of disease. Anatomic and physiologic phenomena touch closely, and indeed at times overlap the pathologic.

CONCLUSIONS.

Of young men in health it may be said:—

1. The knee-jerks vary greatly in their range and rapidity, being often difficult to elicit.
2. The achilles-jerk is constantly present, varies much less than does the knee-jerk, and is seldom difficult to elicit.
3. The conjunctival reflex is extremely variable, being absent or faintly present in half of the cases.
4. The same may be said of the pharyngeal reflex.
5. The pupils are equal.
6. The pupils vary greatly in size, ranging from 2 mm. to 4.5 mm. and averaging 2.76 mm. in the light. The pupillary light reflex varies greatly, the range of the excursion being from scant 0.5 mm. to 3 mm. and the average 1.39 mm.
7. In the accommodation reflex the range of the pupillary excursion also varies greatly and is occasionally absent, the average range being 0.967 mm.
8. Convergence is more or less defective in fully half the cases.
9. The eye-grounds exhibit more or less deep or extensive cupping of the optic nerve with gray stippling in about an eighth of the cases; and in a few of these the appearance is suggestive of beginning gray atrophy.
10. The stereognostic appreciation is uniformly keen.
11. The same may be said of the muscular and spacing senses.

THE SURGICAL TREATMENT OF HALLUX VALGUS AND BUNIONS.¹

BY

JAMES NEWELL, PH.D., M.D., CH.M.,
of Watford, Ont.

Late Professor Therapeutics in the Michigan College of Medicine and Surgery, Detroit; Member of the Michigan Surgical and Pathological Society; Corresponding Member of the Wayne County Medical Society, Detroit; Late Physician to Detroit Emergency Hospital, etc.

The term hallux valgus implies abduction of the great toe. The extent of this abduction is variable, but it is usually to a marked degree. By bunion is meant the swelling and hypertrophy of the tissues over the internal aspect of the metatarsophalangeal articulation of the great toe, and is extended so as to include the hypertrophied head of the metatarsal bone and the overgrown base of the first phalanx. Hallux valgus precedes bunion and is often caused by ill-fitting boots, which are too narrow, causing crowding of the toes. In the natural condition of the great toe, a line drawn through its center and extended backward will be found to run through the middle of the heel, but it is very rare to find in the adult a foot which is normal.

This outward deflection of the great toe uncovers the head of the first metatarsal bone, and with this there is also a slight outward dislocation of the base of the phalanx. Owing to this there ensues an inflammatory condition of the tissues, followed by swelling, hypertrophy, and frequently a false bursa. As the dislocation proceeds, the tendon of the extensor proprius pollicis becomes displaced outward, and when this displacement becomes well marked a distinct exostosis is very frequently formed. These are the causes briefly outlined which lead up to this deformity.

Treatment.—So far as my experience goes, the conclusion has been forced upon me that the palliative or usual treatment resorted to has not been followed by permanent benefit. Of course properly fitting shoes with a straight internal border, roomy at the toes, but with no dead space must be advised. Sometimes also there may be a gouty or rheumatoid arthritis which should receive proper medical treatment.

If seen in the early stage of the disease, which is rare, an appliance to keep the big toe in its proper place may be tried, or a sock having a separate compartment for the great toe. Sometimes placing a roll or wad of cotton between the toes, or the wearing of a boot having a separation or division rising up from the insole, is found of service. Various splints, springs, plasters, traction by elastic, etc., are in use, and will afford relief in the early stage of the disease. When, however, the deformity is well marked, and the uneasiness and pain are severe, it is necessary to proceed to operative measures.

Various operations have been employed in which the relief and benefit which followed was an uncertain quantity. Thus, in such cases, treatment has consisted of a straight incision, removal of the false bursa, and excision of the exostosis by the chisel or bone-forceps, but the result was not what was expected. There are also several other methods which have their advocates.

The operation which I have done and will proceed to outline, has been followed by complete and permanent relief, both of the hallux and bunion. As the operation is radical and a rather extensive one, involving the laying open of the joint and amputation of the head of the first metatarsal bone, it demands thorough and complete asepsis in the field of operation, instruments, hands, dressings, and everything which may come in contact with the wound.

The foot should be thoroughly scrubbed and washed with hot water and soap, and I have found brown soap such as is to be found in every house, to be as good as any. This is followed

¹ Read before the Canadian Medical Association at London, Ont., August 25, 1903.

by bathing with gasolin or oil of turpentine. Wash off with soap and water again, and then apply a 1-500 solution of mercuric chlorid, or a cream of the chlorinated lime and sal soda. Then finally wash off with sterile hot water. Do not forget to give special cleansing and disinfection to the skin between the toes. The hands of operator and assistants must also be thoroughly washed, scrubbed, and sterilized, as may be preferred, not forgetting the interdigital skin and nails. Personally I have a predilection in favor of chlorinated lime and sal soda to sterilize the hands. I find it does not roughen them like mercuric chlorid.

The operation which I do is the "Tubby Operation," and the technic is as follows:

An incision of from 2 to 3 inches long is made on the inner side of the big toe, with its center over the bunion. This incision may be straight or curved, or it may be made to include the skin over the false bursa, if there is one. This false bursa must be excised, before the incision is carried down to the joint, and its contents not allowed to escape and infect the wound.

The incision is now made down to the bone and the tissues are dissected and separated from the bones. This having been done, an assistant thoroughly retracts the tissues, when the joint is freely opened and the ligaments completely divided. It will now be found that the great toe can be easily turned outward, completely exposing the head of the metatarsal bone. As one of the objects is the removal of the head of this bone no difficulty will be experienced in inserting a small metacarpal saw and dividing the bone just behind the articular cartilage. The bone should be sawed through obliquely from above downward and backward. It is of importance to keep this in mind, as it leaves a much better joint. After the removal of the head of the bone, the sharp edges must be cut off with a pair of bone forceps, especially on the outer surface so as to remove any pressure from the branch of the internal plantar nerve. The under surface also requires careful trimming, so as not to be irritated by the sesamoid bones. Any exostosis that may be found on the metatarsal bone should now be removed by bone nippers. The wound should now be sponged out with sterile gauze. I have generally operated by the bloodless method, and have never had to ligate an artery. When bleeding has ceased the wound is closed by silkwormgut sutures. A pad of cotton is then placed between the great and second toes, so as to straighten the big toe, and if it is adducted a little, no harm will result. A light dressing of sterile gauze is now applied and a sheet iron splint placed on the sole of the foot and big toe with a piece turned up between the great and second toes to prevent outward deflection. The part of the splint under the toe is curved upward so as to cause the great toe to point slightly upward. Next a generous quantity of sterile gauze is applied over the foot to absorb any serous or bloody discharge, a bandage is applied to the foot and half way up the leg and the patient placed in bed, with the foot elevated. Should the dressing become soiled it must be removed to prevent wound infection. It is important this should not take place for the results would be bad in more ways than one.

The stitches may be removed in 10 days, the splint and pad reapplied, and the foot dressed as after the operation. When the wound is completely healed, passive movements in the joint are instituted in from 2 to 3 weeks.

The patient may now be allowed to go out, but the splint should not be removed till the end of the month. The pad of cotton between the toes may be kept much longer so as to prevent a return of the hallux valgus.

Bunions are looked upon as among the lesser evils, but their common prevalence, and the trouble and pain of which they are the cause, induce us to seek out a means whereby we may obtain an adequate and permanent cure.

The final result of this operation leaves nothing to be desired. The foot is restored to its normal appearance, the toe is returned to a straight line, but slightly shortened, and the lameness and pain have vanished.

MALIGNANT GROWTH IN THE ABDOMINAL WALL FOLLOWING ABDOMINAL OVARIOTOMY.

BY

GEO. W. KAAH, M.D.,

of Boston, Mass.

Cases of recurrent malignant growth in the abdominal wall following abdominal ovariectomy are not uncommon, yet they are sufficiently rare to merit attention. Halban¹ reports the following case:

A woman, aged 48, had two ovarian cysts removed; the one on the left side was about the size of the fist, that on the right was larger than a man's head. The latter cyst contained a brown serous fluid, and was punctured with a trocar. Both

cysts were unilocular and exhibited numerous excrescences, both upon the outer and inner walls. The peritoneal coat of the uterus, bladder, and intestines was studded with millet seed sized excrescences. The histologic examination showed a papillary cystadenoma of the ovary without any malignant degeneration. The patient was in apparent good health until about 18 months after the operation, when she began to have stabbing pains in the abdomen. Six months later she noticed a growth the size of a hazel nut in the line of the abdominal incision, which gradually increased in size, and she began to lose weight. In October, 1901, more than seven years after the operation, she again appeared at the clinic. The abdomen was enlarged to an even level with the thorax. At the upper part of the line of incision there was a tumor about the size of the palm of the hand, irregular in outline and of uneven surface. Examination showed the uterus atrophied with no abnormal resistance anywhere nor any tenderness; no enlargement of inguinal glands; no ascites. Diagnosis was made of inoculation metastases of abdominal incision following ovariectomy. The tumor was extirpated and histologic examination proved it a typical adenocarcinoma with numerous calcareous deposits.

Halban mentions other cases as occurring in the clinics of Pfannenstiel, Schauta, and others. He divides these cases into three groups:

1. Extirpation of a malignant cyst followed by malignant growth in the abdominal wall.
2. Benign cyst followed by benign growth.
3. Benign cyst followed by malignant growth.

To explain the last group is a difficult matter. Olshausen considers that in the primary, apparently benign cyst, there yet may have been a mixed growth; while Pfannenstiel, upon the basis of an exact histologic examination of a cyst which was benign throughout, considers there may be at first an inoculation of benign cyst particles which secondarily become malignant at the point of inoculation. Halban places his case in the third group, although he recognizes the fact that it is especially in cases of ovarian cystomas that the histologic examination may indicate a benign growth, while the clinical course of growth shows it to be malignant.

In discussing the subject, Chrobak mentions having seen a few cases of metastases in the abdominal wall, but in only one had he seen the patient from beginning to end.

The woman was in labor, and the cyst preventing progress, he punctured it; delivery followed promptly upon the emptying of the cyst. Two or three months later, Billroth operated upon the cyst, which had become as large as a man's head. The examination of the tumor made by Rokitsky proved it sarcoma. At that time stumps were treated extraperitoneally, and this stump was fastened in the lower angle of the incision. A few months later there was a hard, irregular immovable tumor in the upper angle of the incision above the umbilicus. Billroth advised against any further operation. In a few weeks Chrobak again saw the woman and diagnosed diseased mediastinal glands, which the autopsy a short time later proved to be correct.

The case I wish to report in connection with the foregoing cases differs from them in that the recurrence, or rather the inoculation of the abdominal wall, did not occur in the line of incision.

The woman, aged 63, was a widow, and had two children. A cyst of the right ovary as large as a coconut was removed through a median abdominal incision. In its removal not more than half an ounce of its thin brown fluid contents was lost in the abdominal cavity; other than this the cyst was taken out intact, and none of its contents touched the abdominal incision. The uterus and left ovary were atrophied. The pathologist reported the cyst as nonmalignant. Upon her discharge from the hospital she wore an abdominal belt, and after a time noticed a small bunch not larger than a pea above the umbilicus, which she considered due to the irritation from the belt. The bunch grew larger, began to ulcerate and became painful. One year after the first operation she entered the Free Hospital for Women. The bunch now was as large as a lemon, red in color, and with offensive odor. It was not situated in the line of incision, but a little above it, at the umbilicus.

This new growth was excised, including a margin of healthy tissue all around it. It was found to extend through the abdominal wall, and to include a small portion of the omentum, which was also removed.

Pathologic Report.—Large round-cell sarcoma. Six months after this last operation the inguinal glands of both sides were enlarged, and a firm immovable mass discovered in the pelvic cavity. Seven months later the pelvic cavity was practically filled with this firm mass, and the patient suffered from pres-

sure upon the pelvic organs. She died soon afterward. No autopsy.

The fluid contents of the cyst in this case were of the same appearance as in the one reported by Halban, and similar also in apparent benignity. In his case the abdominal wound was inoculated and recurrence occurred there. In this case the wound was not infected, but a very small portion of the cyst contents was left in the abdominal cavity. It is not likely that this small amount of fluid found its way to the peritoneum at the umbilicus, and set up a sarcomatous growth there. It is more probable that it was the focus of the growth in the pelvis which finally proved fatal, the growth at the umbilicus being in fact due to the irritation of the stiff abdominal belt in a woman with a system impregnated with malignant disease.

Sinclair,² in an address upon the subject of cancer, claims that cancer is infectious to the individual already infected with cancer, but to no other. The phenomenon of rapid recurrence in the cicatrice after operation, owing to the contact of the fresh wound with cancerous matter, points to an early cancerous condition of the system; an entirely different matter from the late cancerous cachexia. This fact, established clinically, he feels, has received too little notice.

I believe this case of mine supports Sinclair's claim. Viewing the subject of malignant disease in this light, it is conceivable that the known better ultimate results of high amputation of the cervix as compared with complete hysterectomy for cancer of the uterus may in part be due to less of a strain being put upon the malignantly affected system by the former operation. This leads up to the question as to whether after an operation for malignant disease we give sufficient attention to improving the general system of the patient.

In respect to ovarian cysts there is no doubt of the wisdom of Schauta's statement in discussing Halban's case, that they should be removed intact. A second case which has come under my observation is the following:

A woman aged 39, married and nullipara. At the time of operation eight quarts of ascitic fluid was removed from the abdomen. The peritoneum was studded with papular excrescences and the ovaries were masses each the size of a fist, of polypoid friable tissue. In the removal of these masses some of the fluid contents escaped into the abdominal cavity. The pathologic report was malignant adenoma. The abdominal incision was closed without drainage and healed by first intention; within four months the incision showed evidence of malignant disease and the patient died shortly afterward.

A third case is now under röntgen ray treatment by a colleague at the Free Hospital for Women, with doubtful improvement:

The patient, a woman of 44, noticed, last May, a pain in the lower abdomen when walking. In June the uterus and two ovarian cysts were removed; in one of the cysts there was a nodule of endothelioma. She has now a red elevated hard nodule in the right upper groin with a general hard brawny infiltration extending to the median line.

Here again the recurrence was not in the line of incision but at some distance from it. In a discussion upon the subject of sarcoma, Douglas Graham, of Boston, stated that in his experience it seemed that patients with sarcoma had a smoother and more silky feel to the skin and more subcutaneous elasticity of tissue than normally. If this is so it further confirms Dr. Sinclair's hypothesis of a malignant condition of the system, which is prior to and distinct from its local manifestation. It would mean also that a diagnosis to be early must be based upon something else than localized conditions and symptoms. This systemic condition might explain why all local treatment, surgical or otherwise, is so barren of good results.

SUMMARY OF AN EXPERIMENTAL RESEARCH INTO DIGITALIS IN SHOCK AND COLLAPSE, WITH ILLUSTRATIVE PROTOCOLS.

BY

G. W. CRILE, M.D.,
of Cleveland, Ohio.

In these experiments the fluid extract, the tincture, and digitalin were used. In the normal animal therapeutic doses of digitalis, intravenously administered, caused a rise in the blood-pressure. The rise began after a latent period of half a minute to several minutes and gradually increased until the maximum was reached. The maximum was well sustained for a considerable time. The pressure finally assumed about its previous level. During the ascent, the continuation, and the descent the curve was usually even; the length of the pulse wave was usually increased; the heart's action was considerably increased in force and appreciably diminished in frequency. When given in larger doses or when smaller doses were repeated beyond therapeutic limits, the blood-pressure rose higher and more abruptly. The heart at first beat with greatly increased force and diminished frequency. The intermissions which were sometimes noted were usually the first symptoms of a cardiac breakdown. The latter was manifested by slow, powerful beats, followed by a varying number of rapid weaker contractions, making an irregular blood-pressure curve. If the overstimulation fell short of a fatal breakdown, the intervals of alternation between the slow, powerful contractions and the rapid, weaker ones, increased, later only intermissions appearing; finally the normal rhythm was reestablished. In the experiments in which the overstimulation reached the fatal breakdown, the alternations became more marked and the heart suddenly stopped. The force of the contractions in some instances was so much increased as to raise the thoracic wall and even shake the entire animal. In the experiments in which both vagi and accelerantes had been previously severed, the effects were not so marked. In careful measurements of twenty-eight experiments on single doses, the mean rise in the blood-pressure was 8 mm. In animals reduced to varying degrees of surgical shock, digitalis usually caused a rise in the blood-pressure. When the animal was reduced to such a degree of shock that burning the paw or stimulating the sciatic nerve caused no rise in the blood-pressure, digitalis caused a slight, if any, rise. The highest rise was 10 mm.

When overstimulation was obtained by administering too large a single dose, or by repeating smaller doses, the heart became extremely irregular or the animal died suddenly from cardiac failure. In some instances convulsions occurred.

The respiration, when at all affected, was either impaired or arrested. Death in the digitalis experiments, even in those in which the dosage was only therapeutic, was usually more sudden than in the controls. Although the data do not permit positive statements, it seemed, on the average, that in cases of shock the animal treated by digitalis did not live so long as the controls. It may certainly be stated that they did not live longer than the controls. In the experiments in which the medulla was cocainized and those in which the cord was severed just below the medulla, digitalis caused a distinct rise in the blood-pressure. When the heart had ceased to beat, digitalis introduced by intravenous infusion or by direct injection into the chambers or the walls of the heart did not produce any appreciable effect. The animals showed considerable idiosyncrasy in their reaction to digitalis.

EXPERIMENT 29.—Mongrel dog; weight, 8½ kilos; good condition. Ether anesthesia.

At 10.40, the initial blood-pressure was 140 mm.; pulse, 180; stroke, 11.

At 10.45, 1.3 cc. of tincture of digitalis was injected into the femoral vein.

At 10.46, pulse, 160; stroke, 12 mm.

At 10.48, the foregoing injection was repeated. The blood-pressure remained unchanged. The length of the stroke increased 2 mm.; pulse, 170.

At 10.51, 1.3 cc. (20 m.) of tincture of digitalis was injected.

At 10.54, 1.3 cc. (20 m.) of tincture of digitalis was injected.

At 10.56, blood-pressure, 155 mm.; stroke, 20; pulse, 160. The animal was killed.

EXPERIMENT 30.—Mongrel dog; weight, 11 kilos. Morphine and ether anesthesia. The spinal cord was severed in the lower dorsal region.

At 4.10, blood-pressure, 60 mm.; pulse, 210.

At 4.11, an injection of 1.3 cc. (20 m.) of tincture of digitalis was administered.

At 4.14, blood-pressure, 85 mm.; pulse, 180; respiration, 72.

At 4.17, blood-pressure, 100 mm.; pulse, 160; respiration, 148.

Fig. 5 shows the steady rise in the blood-pressure.

EXPERIMENT 41, 42. Dog 1: Male mongrel; poor condition; weight, 6 kilos. Dog 2: Female mongrel; fair condition; weight, 5 kilos. Ether anesthesia.

At 9.45, the tracheal and carotid canulas were adjusted.

At 10.27, preliminary observations were as follows: Dog 1: Blood-pressure, 134 mm.; stroke, 6 mm.; pulse, 164; respiration, 68. Dog 2: Blood-pressure, 125 mm.; stroke, 6 mm.; pulse, 168; respiration, 52. The animals were reduced to shock by exposing and manipulating the intestines. The femoral vein and the sciatic nerve of each dog were exposed.

At 10.28, dog 1: Blood-pressure, 94 mm.; stroke, 2 mm.; pulse, 152; respiration, 48. Dog 2: Blood-pressure, 75 mm.; stroke, 6 mm.; pulse, 128; respiration, 65.

At 10.30, the sciatic nerves were stimulated, with results as follows: Dog 1: An abrupt rise in the blood-pressure of 2 mm. followed by a slow decline. Dog 2: Slow rise in the blood-pressure of 2.5 mm.

At 10.31, dog 2: .3 cc. (5 m.) of tincture of digitalis was injected.

At 10.32, dog 1: An equal amount of normal saline was injected. Dog 1: Blood-pressure, 100 mm.; stroke, 4 mm.; pulse, 160; respiration, 52. Dog 2: Blood-pressure, 98 mm.; stroke, 5 mm.; pulse, 120; respiration, 64.

At 10.35, the sciatics were stimulated. Dog 1: A rise in the blood-pressure of 8 mm. was noted. Dog 2: A rise in the blood-pressure of 5 mm. was noted. The rise was more abrupt in dog 1.

At 10.47, dog 1: 1.3 cc. (20 m.) of normal saline was injected. Dog 2: .3 cc. (5 m.) of tincture of digitalis was injected. In both animals a gradual rise followed. Dog 1: The blood-pressure rose 8 mm. Dog 2: The blood-pressure rose 22 mm.

At 10.51, the sciatics were stimulated. Dog 1: The blood-pressure rose 6 mm. Dog 2: The blood-pressure rose 5 mm.

At 10.55, dog 2: .3 cc. (5 m.) of tincture of digitalis was injected. Dog 1: 1.3 cc. (20 m.) of saline was injected. Dog 1: The blood-pressure rose 8 mm. Dog 2: The blood-pressure rose 5 mm.

At 11.31, the sciatics were stimulated. Dog 1: A rise in the blood-pressure of 4 mm. followed. Dog 2: A rise in the blood-pressure of 13 mm. followed.

At 11.55, dog 2: .6 cc. (10 m.) of tincture of digitalis was injected. Dog 1: 1.3 cc. (20 m.) of saline was injected.

At 11.55-30, dog 1: Blood-pressure, 96 mm.; stroke, 10 mm.; pulse, 156; respiration, 52. Dog 2: Blood-pressure, 92 mm.; stroke, 4 mm.; pulse, 52; respiration, 144.

At 11.59, dog 1: The sciatic was stimulated.

At 11.55-30, dog 2: The sciatic was stimulated.

At 12.02, dog 1: A rise in the blood-pressure of 8 mm. followed. Dog 2: A rise in the blood-pressure of 5 mm. followed. Dog 1: Repeated clots occurred.

At 1.10, dog 1 died of an excessive dose of $MgSO_4$.

At 1.53-30, dog 2: .6 cc. (10 m.) of tincture of digitalis was injected. Blood-pressure, 96 mm.; stroke, 4 mm.; pulse, 144; respiration, 36.

At 1.55, dog 2, the sciatics were stimulated. An abrupt rise in the blood-pressure of 17 mm. occurred.

At 3.00, dog 2: .6 cc. (10 m.) of tincture of digitalis was injected. Blood-pressure, 94 mm.; stroke, 4 mm.; pulse, 144; respiration, 40.

At 3.03, the sciatics were stimulated. A rise in the blood-pressure of 9 mm. followed.

At 3.03-30, the sciatics were electrically stimulated. A rise in the blood-pressure of 14 mm. followed.

At 4.39, dog 2: .6 cc. (10 m.) of tincture of digitalis was injected. Blood-pressure, 70 mm.; stroke, 6 mm.; pulse, 104; respiration, 20.

At 4.44, the sciatics were stimulated. A rise in the blood-pressure of 2 mm. occurred.

At 5.00, dog 2 died of respiratory failure.

Johns Hopkins Hospital and Mr. Rockefeller.—John D. Rockefeller has given to the Johns Hopkins Hospital the sum of \$500,000, and the amount has been accepted by the board of trustees of that institution. The income of the hospital was seriously affected by the destruction of many houses belonging to it in the recent fire, upon which there was inadequate insurance. The expressed purpose of Mr. Rockefeller's gift is to restore that income to its original proportions and enable the hospital to keep up the charitable treatment which it has maintained in the past.

THE IMPORTANCE OF CONSIDERING THE ELEMENT OF VASOMOTOR INSTABILITY IN ESTIMATING THE SIGNIFICANCE OF IRREGULARITY OF CARDIAC RHYTHM.

BY

LOUIS FAUGERES BISHOP, A. M., M. D.,

of New York City.

Physician to the Lincoln Hospital, New York.

The frequent discrepancies between the heart-sounds as heard by the stethoscope and the pulse as determined by palpation must have impressed all observers. It has been a matter of surprise that hearts, which, by their sounds, seemed to be doing good work, were often accompanied by a pulse giving a poor impression, and, on the other hand, cases showing irregularities of the heart-sounds have been associated with a pulse showing a fair degree of regularity.

When it is remembered that, in the light of evolution, the heart is constructed of the same elements as the bloodvessels and is only a differentiation of the circulatory tube, and when it is appreciated that not only the blood of the heart but the blood of the whole circulation is surrounded by a muscular envelope that maintains its pressure, it can easily be seen that in palpating any portion of this blood-containing system, the variations in pressure will be a complex of the whole envelope and not merely of its strongest portion.

The vasomotor system is much more liable to disorder than the heart and the heart is able to compensate for a good deal of misbehavior on the part of the vessels, but in compensating, it often appears to be misbehaving itself. Thus, one may fall into the error of predicating disease of the heart-muscle when the trouble really is a functional derangement of the bloodvessels. In many of the cases that are strikingly benefited by the Nauheim treatment the results are undoubtedly obtained by a restoration of the peripheral circulation and the relief of the heart from a struggle to compensate for it.

Not only clinical but pathologic study confirms the fact that diseases of this class, including myocarditis and nephritis, have their origin most often in degeneration of the bloodvessels, at first functional and then organic. The coronary arteries of the heart become involved and then the heart-muscle suffers. The vasomotor of the bloodvessels suffer and then the larger vessels, so even in the early stages of circulatory symptoms, the relationships should be appreciated and the hygiene of the peripheral circulation becomes a matter of serious supervision.

Floating Hospitals for Pulmonary Diseases.—Recent news from Vienna states that the Austrian-Hungarian Floating Sanitarium Company, of London and Vienna, is meeting with considerable financial encouragement owing to the prominence of its chief director, Dr. Semon, physician to King Edward. The company intends to build big hospital steamers to travel about the Austrian, Italian, and French coasts—anywhere where it is warm and sunny. The accommodations will be principally reserved for people with lung trouble, and elaborate plans for their relief and cure are being worked out by eminent physicians here and in England. The company expects to start with a capital of \$5,000,000. It has procured favorable opinions from many medical authorities. M. Murali is the chief promoter.

N-Rays Exist in Sunlight.—Information from Paris, under date of April 3, says: Further experiments with N-rays, made here by MM. Blondelot and Charpentier, prove the rays to be a part of the invisible spectrum of sunlight, a little more ultra than the ultraviolet rays. They are between the heat and electric rays, slower than rays of radiant heat and faster than Hertzian waves. The N-rays can pass through aluminum as sunlight does through glass, and can be focused by an aluminum lens. They can be spontaneously produced from wood or glass, when twisted or subjected to pressure. Tempered steel limits them continuously. Professor Charpentier discovered that the human body emits the rays in quantities proportionate to the activity of that part of the body whence they come. He also proved that they are emitted from the speech center of the brain whenever a person speaks. When the speaker emits rays they vary according to the pitch of the note.

2.—Retrodisplacements of the Uterus.—C. W. Oviatt agrees with the experienced gynecologists that uncomplicated retrodisplacements rarely cause disturbing symptoms. In the exceptional cases a pessary with possibly pelvic massage and postural treatment may be all that is required. Complications should be carefully sought for and the method selected that will best enable the surgeon to deal with them. The writer prefers the operation devised by G. H. Noble for suturing the round ligaments in the abdominal wall. Through the skin, fat, and aponeurosis an incision is made transversely $1\frac{1}{2}$ inches above the pubis to the outer border of the recti. The recti and peritoneum are separated vertically, the round ligament grasped and made taut, and at the outer edge of the recti the point of artery forceps is forced through the sheath of the muscles, but not into the abdomen, and opened to make an aperture to admit the finger which is hooked under the taut extraperitoneal portion of the round ligaments. The sheath of the ligaments is split open by blunt dissection and it and the peritoneum stripped back in the direction of the uterus. After closing the vertical incision the two ligaments are drawn out of the openings approximated in front of the recti and tied. The cut edges of the aponeurosis are then stitched together, the continuous suture including the ligament and a little of the muscle on each side as well. [H.M.]

3.—Relation of the Appendix to Perforation in Typhoid.—L. J. Hammond thinks our greatest possibilities in lowering the mortality from perforation lie in removal of predisposing conditions. Beside the 5% arising from the appendix alone, there is a large number occurring in the ileum and ascending colon that can be directly traced to preexisting disease of the appendix. He reports cases demonstrating this, the tension from adhesions causing rents in the ulcerated patches. Typhoid is sure to light up the old inflammation. Therefore, when the earliest symptoms in typhoid are pain to the right of the hypogastric region, with tenderness, nausea or vomiting, aching in the loin, anorexia, and rigidity of the right rectus muscle, this should be suspected, knowing that the right iliac fossa is not tender until the seventh or eighth day in uncomplicated typhoid. Immediate laparotomy seems the only wise course, removing the appendix, and freeing agglutinated coils of intestine. [H.M.]

4, 5.—See *American Medicine*, Vol. V, No. 20, p. 781.

6.—Insufficiencia Pylori.—M. I. Knapp believes the recognition of this as a cause of chronic dyspepsia of paramount importance. One hour after Ewald's test-breakfast there should be from 30 cc. to 50 cc. of chyme. Insufficiencia pylori is the condition in which nothing or possibly but 1 cc. or 2 cc. of chyme is aspirated. The larger the quantity and the finer the pulverization the longer did the pylorus offer resistance, the longer was it closed. And since protracted closure could not exist without active peristalsis a large quantity of chyme in which a "floury layer" is present signifies an active hypertonic stomach. This is contrary to the general view which attributes such chyme to atony. The stenosis indicated is due to irritation. Coarse chyme indicates insufficient closure preventing the ingesta being acted on dynamically. In the last stage the food rushes immediately past the pylorus, the patient practically having no stomach. The predominant symptoms are due to gas in the bowel. The appetite is variable. Vomiting may be present. Several test-meals with aspiration at varying

periods are necessary for exact diagnosis. Inflation may be of some avail. In the last stages the stomach cannot be inflated. Loss of teeth must be supplanted by artificial ones. When this is impossible, cereals and vegetables should be eaten in the form of puree. Meat should be ground up in a machine. Food that develops gas should be avoided. Alkalies should be given at the time the stomach is emptied. Pancreatin and papain must be fresh. Strychnin in large doses is the most important drug. [H.M.]

7.—Therapeutics of Insanity.—O. Everts thinks our medication not in advance of that of Hippocrates. Patients are narcotized to a perilous degree. Loss of blood can be more easily recovered from than repeated intoxication. Hygienic therapeutics are in accord with common sense, of which the most important relate to air and water. Massage and electricity fail as suggestive therapeutics among the insane. Occupation and manual labor are beneficial to the chronically insane. Disciplinary therapeutics are second only to hygiene. The question is as to the method of restraint, whether by mechanical appliances, paralyzing drugs, or moral influences. Some are incapable of recognizing the latter. Restraint by an attendant is more exasperating than by an appliance. Prohibition instead of regulation of the use of the latter was an error. The use of narcotics has diminished the ratio of recoveries. [H.M.]

1. Infectious Arthritis. JOEL E. GOLDTHWAIT.
2. Some Points on Diagnosis and Treatment of Certain Neglected Minor Surgical Lesions. E. A. CODMAN.
3. Radical Cure of Inguinal Hernia. JOHN O'CONNOR.

1.—Infectious Arthritis.—Joel E. Goldthwait holds that infectious arthritis is rarely primary, but is usually a sequel of some other disease, representing probably an extension of the affection, in this respect similar to the present opinion with reference to the cause of mastoid and middle-ear disease. Infectious arthritis may result from any of the pus-producing organisms, and the type of lesion will depend upon the tissue and organism involved. The disease may be mild and short, with complete recovery, or severe, with even a fatal termination; one or many of the joints may be affected, and there may be destruction of articulation. Skiagraphic and photographic plates accompany the article, illustrating the deformity and destruction in various joints. The pneumococcus, streptococcus, and typhoid germs may cause marked destructive changes in the bones as well as the soft parts. The gonococcus rarely causes bone changes, but is associated with much thickening of the capsule and interference with joint function. In the difficult diagnosis of infectious arthritis from the other types of rheumatoid disease, in case the history, the general appearance of the patient, and the local lesion are not distinct, the röntgen rays are of importance. In infectious arthritis without suppuration the bones are of normal density, the cartilage is present and of normal thickness, and though the joints may be ankylosed, the ankylosis is due to the adhesions which have resulted as part of the inflammation. Detailed histories of 18 cases are reported by the author. [A.B.C.]

2.—Neglected Minor Surgical Lesions.—E. A. Codman says among the frequently unrecognized lesions seen in the outpatient surgical department are certain unrecognized fractures which he has learned to distinguish from sprains. The old statement, that a sprain is worse than a break, has arisen from the fact that in many of these instances an unrecognized fracture exists instead of a sprain. Among the most common of the unrecognized fractures is that of the scaphoid bone of the wrist. A typical case is reported. Diagnosis is made sure by the röntgen rays. Bony union does not take place and the bony callus is so large as to interfere with the function of the wrist and destroy the normal contour; dislocation of the semilunar bone of the wrist sometimes occurs, especially in case the scaphoid is fractured. Early tuberculosis of the wrist-joint is often not recognized, as are also rheumatoid, and osteoid arthritis at this joint. At the shoulder-joint various lesions may occur which are obscure and difficult to diagnose; unrecognized

ognized fractures in this vicinity are not uncommon, especially of the greater and lesser tuberosities of the humerus. Another region of interest is the ankle-joint. Codman has learned lately to detect fractures in this region, in which the old signs failed and which used to be called sprains. One of these is impacted fracture of the os calcis. Points in diagnosis are: (1) The history of fall on the foot or heel; (2) tenderness over the os calcis; (3) ecchymosis above the heel on both sides of the foot; (4) shortening of distance between the malleoli and the floor as compared with the other foot. [A.B.C.]

3.—Radical Cure of Inguinal Hernia.—John O'Connor, of Buenos Ayres, reports satisfactory results in a method of operation practised on 50 patients. The incision, isolation, and removal of the sac is after the usual manner; the remainder of the operation, briefly described, is as follows: The conjoined tendon and Gimbernat's ligament are exposed, and with left index finger in canal as a guide, four "strong" fishing-gut sutures are passed from within outward, one-third inch apart, through the projecting ledge of Gimbernat and external oblique, the ends of sutures are retained outside external oblique. The free ends are threaded on a hernia needle with an opposite curve and are carried upward from within outward through conjoined tendon. The ends of these sutures are similarly retained outside sheath of tendon. A straight Reverdin needle is entered through each suture hole in tendon, passed across beneath aponeurosis and emerges at corresponding suture hole in external oblique, the end of this part of suture is caught in needle or forceps, drawn across and out through suture hole in conjoined tendon; thus both ends of each suture emerge from the same aperture in tendon, excepting the fourth or lowest suture, which is only partially submuscular in that it crosses in front of external ring. These sutures are tied with sufficient force so as to approximate the tendon and Gimbernat. The ends of sutures are snipped off and the knots retreat into substance of tendon and each little stitch aperture in sheath of latter is closed by a fine catgut suture. [A.B.C.]

1. The Tuberculosis Hospitals of the New York State Hospitals for the Insane. FREDERICK PETERSON.
2. The Deficient Urea Excretion in Gout and Lithemia. RICHARD K. MACALESTER.
3. Operation for Congenital Saddle-nose by Introduction of a Celluloid Plate. JOSEPH WIENER, JR.
4. The Bladder in Health and Disease, as Demonstrated by the Cystoscope. HENRY G. SPOONER.

2.—Deficient Urea Excretion in Gout and Lithemia.—R. K. Macalester finds as the result of his investigations that persistent deficient urea excretion is always present in chronic gouty conditions. The total urea output is considerably lower than in chronic Bright's disease, about two-thirds of the amount in other miscellaneous chronic disorders, and only about three-fifths of the quantity excreted in health. Deficient urea excretion is important in differentiating between gouty and chronic rheumatic troubles, and between lithemia and certain nervous conditions dependent on other causes. It is not present in chronic rheumatic conditions, urinary analyses not deviating materially from normal. It points to perverted hepatic metabolism and lends color to the Murchison theory of gout, there being in the cases discussed no evidence of kidney trouble. A diminished uric acid excretion is to a certain degree commensurate with that of urea. Gout, goutiness, and lithemia are of the same origin, and but modifications of the same disorder. Chronic gouty conditions are in general more amenable to treatment, especially to balneotherapy, than chronic rheumatic affections. [H.M.]

3.—Celluloid Plate for Saddle-nose.—J. Wiener states that subcutaneous injection of paraffin to correct nasal deformity are not altogether satisfactory. Several cases of embolism have been reported occasionally followed by serious lesion. The introduction of a celluloid plate is simple, safe and efficacious. A case in point is reported. It is now three years since the introduction of the celluloid plate and the results have been entirely satisfactory. The patient was a man of 35; saddle-nose was congenital. An incision was made a quarter

inch long, in the median line on the under surface of the nose. Through this small incision, with iridectomy scissors, a subcutaneous flap was made over the depressed bridge of the nose. A piece of celluloid about half an inch wide, an inch long, and a thirtieth of an inch thick, was sterilized by boiling in soda solution. Taking it out of the hot solution, the celluloid was readily molded to the shape of the bridge of the nose. The plate was then introduced through the incision, and pushed upward until it occupied the space corresponding to the subcutaneous flap. The patient stated he had had no annoyance from the plate subsequent to the operation. [A.B.C.]

4.—The Bladder as Demonstrated by the Cystoscope.—Henry G. Spooner devotes a considerable portion of his article to a discussion of the mechanism of the cystoscope and instructions as to how it should be used. This instrument has shown that cystitis of gonorrheal origin is a localized process encompassing the neck of the bladder and the trigonum, but never spreading further. Miliary tubercles are formed by the deposition and growth of the tubercle bacilli. These tubercles can be seen in the form of small round gray elevations, surrounded by hyperemic areas. Later by the process of cheesy degeneration these tubercles ulcerate, and as their walls coalesce, extensive ulcerations of the mucosa and submucosa are formed. After inflammation of the bladder, particularly the gonorrheal form, the region of the trigonum shows a remarkable tendency to papillary proliferation. Fenwick's statistics, based upon an examination of all the bladders contained in the museums of England, Scotland and Ireland show that single growths of the bladder occur in 86% of the cases in the inferior zone. They are found at the right ureteral orifice in 43%; at the left ureteral orifice in 26%, and on the interureteral line in 10% of the cases; 90% of the fibroma papillare or villous growths occur at the ureteral orifice. These small villous growths are the starting points of most of the tumors of the bladder. [A.B.C.]

4.—Epidemic Trachoma.—In discussing the subject of trachoma, E. M. Alger says the present epidemic among school children is nothing more than that of follicular conjunctivitis. They have none of the symptoms of trachoma, subjective or objective, except the soft granulations. He says there is absolutely no evidence of contagion that would not apply equally well to heat prostration or to enteritis. Alger believes that atmospheric dirt must play a very large part in its etiology. In most cases the glands in the neck are enlarged, and it is notorious that this class of children have a disproportionate number of adenoid growths in the pharynx. The granulations usually disappear completely in a few weeks' time under the simplest kind of treatment. [C.A.O.]

5.—Physiology and Pathology of Biliary Secretion.—Hubert Richardson states the physiologic action of the bile salts as follows: 1. Injected in small doses into the blood-stream, they produce a widespread disintegration of the red corpuscles with a liberation of hemoglobin; brought into contact with cells of the body, they cause their disintegration. 2. Blood in which there is a certain amount of bile, agglutinates the typhoid bacillus, and to a certain extent *Bacillus coli communis*. 3. Administered by the mouth they have a cholagogue action, and are, in fact, the only drugs which have the power to produce an increased flow of bile, both solid and liquid constituents being increased. 4. The presence of the bile salts in the blood acts as a stimulus to the liver cells. 5. In small doses

they aid coagulation. 6. In large doses they arrest coagulation. 7. In very small doses they act as vasodilators. 8. In large doses they act as vasoconstrictors. 9. They reduce motor and sensory irritability. 10. They slow the heart-beat by direct action on the heart muscle and the cardiac ganglia. 11. They act on the higher cerebral centers, causing coma and death. Under physiologic conditions, Numbers 1, 3, 4, 5 and 7 may be considered their normal action, while 6, 8, 9, 10 and 11 are pathologic and due to excess in the blood. [C.A.O.]

1.—Ulcer and Cancer of the Stomach from a Surgical Standpoint.—William J. Mayo says chronic ulcer of the duodenum should be classed with gastric ulcer. In 39 cases which have come under his care at the operating table, 32 were in males. Of the combined series of gastric and duodenal ulcers occurring in his experience, 12% were duodenal and 88% gastric. Welch found in 793 autopsies that chronic gastric ulcer occurred in women in 60% of cases and in men in 40%, which is similar to Mayo's experience in over 300 cases. Can cancer of the stomach be cured by operation? Murphy collected 189 cases operated upon by seven different surgeons, and the deaths as result of operation were 26, or 15%; and the patients surviving the three-year limit were 17, or about 8%. Can the diagnosis be made in time by medical means? No; in the vast majority of cases exploratory incision is the only means by which a definite diagnosis can be made. The presence of a tumor in the pyloric region does not contraindicate operation; it may, in fact, be a beneficent check producing timely stenosis at the pylorus. The laboratory diagnosis of cancer of the stomach has little importance during the operable period, because the disease is so slight as to interfere little with the secretions. Mikulicz has shown that with cancer at the pylorus the entire lesser curvature must be removed, whereas Cuneo has demonstrated that the glands which drain the greater curvature are near the pylorus and that the lymph current is from left to right, showing that excision of the pylorus with the lesser curvature may be done without sacrificing the greater curvature and the fundus. His conclusions are that cancer of the stomach can be cured without excessive mortality only when exploratory operation is undertaken early; palliative treatment is but a prolongation of a hopeless existence. [A.B.C.]

2.—Otitis Media in Croupous Pneumonia.—Nathan G. Ward says the relationship of a complicating otitis media to the systemic condition may be as follows: 1. One who has otorrhea develops the systemic infection. 2. One who has otitis previously but has been apparently well for a long while suffers a recurrence. 3. Otitis as a primary manifestation, the systemic disease following. 4. Otitis as a complication or sequel to the systemic infection. 5. The otitic infection as a cause of the systemic infection or general pyemia. These he takes up separately and considers at some length. Otitis media complicates pneumonia more frequently than is suspected. In Netter's 20 cases of otitis, 14 had pneumonia; in Hartman's 36 cases of otitis, 10 had pneumonia. Rasch's 43 cases of pneumonia, 42 had otitis. Teichman's 73 cases of pneumonia, 34 had otitis, and Wilson's 71 cases of pneumonia, 8% had otitis. Ponfick's 11 autopsies on pneumonia cases, 10 had otitis. It is interesting to note that otitis media, complicating pneumonia, practically always precedes this affection. He reports in detail the history of a case illustrative of his points in the discussion. [A.B.C.]

3.—Hepatectomy for Tuberculoma of the Liver.—

Joseph Ransohoff discusses at length hepatectomy for tumors of the liver, mainly, of course, for malignant disease of that organ. According to Keen's table, the mortality of all liver resections is 15%; according to other authors, the mortality is higher. Ransohoff reports having performed hepatectomy for a tumor of the liver. The patient was a man of 36 who, 10 years previously, had the left testicle removed for tuberculosis; since then he had enjoyed good health until the past four months. During the latter period he experienced a sense of weight and pain in the region of the stomach, which he attributed to dyspepsia. During the past two months he had noticed a tumor growing under the tip of the scrotum. Physical examination showed a tumor in the epigastric region, which was movable, irregular in outline, and of considerable size. Laparotomy showed that the tumor was embedded in the left lobe of the liver; there was no extension to surrounding organs and no enlarged lymph-nodes. The left lobe of the liver was brought into the abdominal wound and anchored by two large bullet-pointed probes transfixing it, and the application of an elastic tube to form a pedicle. The day following, the left lobe was cut away with a thermocautery without the loss of blood, though the patient grew worse and died on the sixth day after the operation. A microscopic examination of the tumor showed it to be tuberculous in origin. [A.B.C.]

4.—Ophthalmology, Otology and Dentistry.—F. Allport reviews in a general way the reported instances of relation between the teeth, eyes and ears by direct continuity of tissue and by reflex irritation, including toothache cured by lenses and prisms, phlyctenular keratitis, conjunctivitis and otitis due to teething, toothache, as a prodrome of glaucoma, strabismus and especially diminished or suspended accommodation, etc., from dental irritation. The prolonged interstitial keratitis of congenital syphilis may be due more to the sensitive teeth than the underlying taint. It is improbable a diseased mouth will cause reflex disturbances without the morbid oral condition being manifested both subjectively and objectively. It is the relationship that is apt to be overlooked. The range of ear diseases so produced is more limited probably because there are fewer ear than eye diseases. The affections are principally myringitis, earaches, sensitiveness of the canal, hyperesthesia of hearing, deafness, furuncles and eczema of the canals. In lancing gums for otalgia the incision should completely liberate the tooth. The writer is sceptical of so-called reflexes in which intense inflammatory conditions are present, these being due to migration of infection. He urges eye and ear surgeons to carefully examine the mouth as a matter of routine. Boards of Health and school boards should appoint dentists who may quickly, yet efficiently, examine public school children once yearly. [H.M.]

5.—Cures for Tuberculosis.—J. E. Stubbert describes the treatment of 150 years ago and the various present-day methods including drugs, light, electricity, water, serum, intravenous and subcutaneous injections, inhalations, etc. With our present knowledge diet, hygiene, and fresh air are universally accepted as the foundation of all scientific treatment, although by themselves they are not sufficient but must be supplemented by symptomatic treatment in the way of antiseptics, tonics and surgical interference when necessary. The probability is that within three years we will see notable advances in immunization and the stimulating effect of light. [H.M.]

6.—Hysteria and Organic Disease.—W. B. Noyes and R. C. Newton note that earlier writers sought for and not infrequently found causes and symptoms that were distinctly organic. More recently chemic and cytologic changes in the tissues have been looked for. The trend of the French school has been to psychologic interpretation explaining its etiology in terms of suggestion, and its primary symptomatology in the line of fixed ideas. In their extreme, these hysterical psychoses resemble paranoia, or other definite insanities may develop. A diathesis of hysterical contracture is apt to be present. Vasomotor phenomena, such as flushes, morbid blushing, sensations of heat or cold occur. If these take place in the sympathetic system, serious trouble from some internal organ may occur, such as flatulence, palpitation, etc. Death may be caused without lesion. Edema of the extremities or gangrene may develop.

Dermatoses are frequent, especially urticaria. When anorexia becomes a symptom, the symptoms of starvation, especially anemia, result. In old people hysteria is associated with arteriosclerosis, etc. The latter does not cause the hysteria, but the hysteric diathesis is revealed by it. Menstrual depression is especially liable to develop definite hysteria. It is difficult to state which is the primary and which the secondary factor in hysteric "female complaints." A painful area similar to the sensitive ovary is frequently seen in male hysterics. Chorea and epilepsy often breed hysteria. Tabes, hemiplegia, definite muscular dystrophies, alcoholism may all have distinctly hysteric symptoms grafted on them. [H.M.]

7.—Varieties of Pulmonary Tuberculosis.—J. Perkins finds that most textbooks give no divisions which are of practical value in prognosis and treatment. Treatment which will cure some is a positive injury to others. The writer makes the following classification: 1. Localized fibrous form. These are favorable. There is little or no necrosis and little mixed infection. These can endure the most vigorous treatment. Cavities and hemorrhages may occur and caseous matter be expelled and yet the disease remain localized. 2. Fibrocaseous form. A considerable portion of lung may be affected followed by a cavity and contraction. The patient may live a long time in fair comfort, but with shortmindedness and debility. Dust, smoke, and all excesses must be avoided. 3. Fibroid phthisis—generalized fibrous form. These run a chronic course and are found chiefly among those exposed to irritating dust. 4. Phthisis florida. This is without formation of fibrous tissue, infection is profound and active, and absorption is marked. The patient dies of toxemia without the disease spreading to other organs. 5. Chronic parenchymatous tuberculosis. The onset is insidious, being generally diagnosed as anemia, debility or bronchitis. Although there is thickening of the alveolar walls there is no shutting off by fibrous formation. The general symptoms are marked compared with the physical signs. It is less rapid, though little less fatal than phthisis florida and patients should not be sent from home. 6. Acute miliary form. This does not advance to dulness and mucous rales before the system is overwhelmed by the toxins. [H.M.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

The value of radiodiagnosis has recently been discussed by Dr. Laignel-Lavastine¹ who enumerates five methods of utilization of the phenomena of "radiology:" Radioscopy, radiography, stereoscopic radiography, stereoscopic radioscopy, and endodioscopy. As the last term is not self-explanatory, it may be well to inform those less familiar with such mysteries, that it is the invention of M. Bouchacourt, and applied by him to denote a new method of excitation of a Crookes' tube by means of an electric current of which the negative pole only is in a state of tension, and so applied as "unipolar excitation of röntgen tubes in the natural cavities." After discussion of results obtained in detection of foreign bodies which are fairly familiar to all our readers, Dr. Laignel-Lavastine discusses the results obtained in lesions of the limbs. His conclusions are as follows:

Fractures are revealed by the appearances now familiar to every surgeon; but, where overriding of the fragments exists, radiography may fail to display its existence, except the limb is examined in various planes. The presence of another bone in the line of transmission of the rays has a similar deceptive effect. Subperiosteal fractures may be completely invisible. If it is exceptional that radiography does not display a fracture diagnosed by the usual methods, the inverse error is extremely frequent. The presence of callus is revealed by the röntgen rays about the twelfth day, when a light shadow begins to appear. Alterations in the osseous tissues are nearly always revealed; rarefying osteitis by an abnormal transparency; osteomalacia by an almost complete disappearance of the usual shadow; condensing osteitis by an accentuation of the same. Luxations—both partial and complete—are necessarily portrayed with vivid distinctness. The existence of

osteomyelitis in the early stages displays nothing abnormal; but the formation of a transparent area about the tenth day indicates the destruction of bone tissue which accompanies the formation of pus. Tuberculous deposits are indicated by clear spots surrounded by a more or less deeply shaded zone due to osteitis—condensing or rarefying. Syphilitic changes are indicated by clear spots; but, being nearly always accompanied by a rarefying osteitis, such patches are masked by a fusiform margin of dark shading—of ill-defined structure; either completely homogeneous or enclosing some clear spots. The most frequent of the osseous changes of leprosy is indicated by the extreme transparency of the phalanges of the fingers. In Paget's disease, the deformed bones display a considerable amount of thickening of the compact tissue. In cases of akromegaly, M. Bécère has obtained some beautiful skiagrams of the head in the sagittal position, showing the pituitary fossa very much widened, the frontal sinuses abnormally dilated, and the cranial wall in the neighborhood of the anteroposterior median plane greatly—and unequally—thickened. Specimens of rickets display the tardy ossification of the epiphyses, with thickening, and slow union of the epiphysary cartilages. There are frequently observed in the adjacent parts of the diaphysis some irregular dark lines produced by stratification of the osseous tissue. In cases of cretinism, the striking feature is the great distances which separate the bones at the articulations; the epiphyses remain completely cartilaginous for a long period. Osteosarcoma is characterized by a well-defined clear patch. In cases of acute arthritis, pus appears less opaque than a simple serous effusion. In a radiographic study of subjects of chronic rheumatism, made by Barjon, in 1897, the interarticular line of clearness gradually diminished, and at last disappeared. In the advanced stages, the osseous tissue appears to become more dense. The nodosities of Heberden and of Bouchard are well shown in typical cases. The tophi of gout are transparent; and, accordingly, there is a startling contrast between the outer appearance of a gouty hand or foot and its radiographic image. The tabetic arthropathies display a rarefaction of the articular extremities of the bones, coexisting with an exuberant osseous vegetation, and ossification of the capsule, ligaments, and tendons. Cases of syringomyelia show disseminated clear patches in the metacarpal bones and phalanges, especially in the neighborhood of the epiphyses. Radiographic examination of specimens of tuberculous arthritis show nothing definitely abnormal; the whole articular cavity appears darker, and the adjacent portions of the bones cast a lighter shade.

Radiodiagnosis in Lesions of the Head, Neck, and Body-cavities.—With regard to the radiology of the head, neck and trunk, the utility of its application varies greatly with the region. That of the head is obviously almost limited to modifications of the brain case itself. As M. Bécère has well put it, if the röntgen rays show a ball of lead in a flask of wood, they do not reveal the presence of a ball of wood within a leaden flask. A portion of the nasopharyngeal cavity and pharynx can be distinguished. The accessory nasal cavities are clearly visible, and above all, the frontal sinuses. In otology, the röntgen rays are not applicable. In the domain of odontology, the teeth can be easily studied by placing the radiographic plate within the mouth. The dental germs can be seen, the enamel throws a darker shadow than does the dentine. The orbital cavity can be well examined by lateral application of the rays; and, accordingly, their employment for the detection of foreign bodies is very useful in ophthalmic practice. The fact of the approximately equal transparency of the abdominal organs to the röntgen rays, combines, with the great mobility of most, to render their radiographic tracing so very unsatisfactory. Radioscopic examination, on the other hand, displays very instructively their displacements during the movements of respiration, and under the influence of pressure applied by the muscular walls of the abdomen, or from without. The ingestion of opaque substances, too, such as the salts of bismuth, enables the observer to study the intestinal movements with great advantage. The exploration of the thorax forms a specially rich domain of observation with the aid of the röntgen rays. As Professor Landouzy has well put it, this mode of examining the thoracic walls and their contents would have specially merited the name of *stethoscopy* had not Laennec previously fixed the sense of that appellation for all time. It adds the more reliable testimony of the eyes to that of the ears, while it displays the existence of deep-seated lesions of which the existence could never

¹ Gazette des Hôpitaux, January 16, 1904.

have been ascertained by any of the previously known methods of examination. In exploration of the thorax, more than in any other region of the body, the first place must be given to radioscopy. In such investigations the use of a diaphragm of lead is indispensable. It is also of great importance to be able to vary the penetrating power of the rays. This can be effected by means of the "osmo-regulateur," of Villard. The movements of the thoracic segment of the skeleton, of the diaphragm, and of the enclosed heart and lungs can thus be studied with vivid clearness. Radiography of the thorax gives a precision to the diagnosis of early, deep-seated tuberculous deposits, which had previously been altogether unattainable. A diminution of transparency is noticeable before any signs are discoverable by inspection, palpation, or percussion, and when auscultation shows but a slight roughening of the respiratory sounds. In this connection it should be remembered that Williams has pointed out that in the normal state the apex of the right lung is less transparent than that of the left. The same observer has stated that diminished excursion of the diaphragm on the affected side is sometimes the very earliest observable sign in cases of incipient tuberculous deposit. The various other forms of solidification of the lung tissue, of pleural thickening, etc., give, of course, still more definite local signs. Pleural effusion offers a well-marked shadow. Pneumothorax gives increased transparency. Hydrothorax or pyopneumothorax displays a field which has been aptly compared by Williams to the shadow of a half-filled ink-bottle. And a specially interesting see-saw movement is also seen, from the fact that with each inspiration the diaphragm descends on the sound side, while the upper surface of the liquid rises on the affected one. The evidence of localized effusions is, of course, less satisfactory. Diaphragmatic pleurisy gives a thickening of the shadow of the diaphragm, more clearly defined, of course, on the left side. Mediastinal pleurisy offers a deepening of the median shadow. The shadow of interlobular pleural thickening is visible only when its plane is placed in the plane of the rays normal to the screen. This fact has been very skilfully demonstrated by M. Bécèle.

Orthodiagraphy is a term devised to denote the mode of determining by the aid of the röntgen rays, the exact dimensions of one of the internal organs by the shadow which it throws upon the fluorescent screen. It is especially applicable to examination of the heart. Exaggerated aortic pulsations are, of course, observable in various conditions: Syndrome of Basedow, chronic saturnism, ventricular hypertrophy, etc. The right oblique anterior position must be resorted to in cases of suspected aortic aneurysm. Tracheobronchial adenopathy is already demonstrable. An esophageal shadow can only be obtained by getting the individual to swallow some opaque substance, such as salts of bismuth, lead, or mercury. Subnitrate of bismuth is oftenest used. Many other minor are discussed by Dr. Laignel-Lavastine in this communication, which is one of the most valuable that we have yet perused on this very important and interesting subject.

Tobacco in Recent Therapeutics.—The unique influence which tobacco has for so long a period exercised on the domestic and commercial history of the human race often causes us to lose sight of the hygienic and therapeutic properties, which have been in various ages attributed to "the weed." That tobacco smoke enjoyed a massive reputation as a deodorizer and disinfectant long before the invention of bacteriologic pathology is well known to all those who have been curious enough to investigate the history of the subject. The establishment of its reputation as a preventive of the dissemination of the virus of plague was effectively rooted in the English literature of the latter half of the seventeenth century. During the terrible epidemic of the plague

which visited and wasted London in 1665–66, the Angel of Death passed over the doors of the tobaccoconists' shops. And the visitation of Hamburg by cholera, a few years ago, left a corresponding record of the immunity of those privileged establishments against the entrance of that dire enemy to human life. Accordingly, tobacco smoke has, within recent date, been made the subject of crucial bacteriologic experiment; but the results of the strictly "scientific" investigations do not appear to have been at all so convincingly demonstrative as those which nature had carried out on so vast a scale by the much cruder methods to which we have referred. The depressing effect of the introduction of even minute portions of tobacco into the rectum was extensively utilized before the discovery of general anesthetics for the production of the muscular relaxation necessary to reduction of the major dislocations. An infusion was used as an enema for this purpose; and sometimes, too, with good effect in lowering vascular tension in cases of very acute inflammations. And the same striking effect in producing general muscular relaxation suggested the researches which led to the establishment of its alkaloid active principle, nicotine, as an antidote of unique value in cases of poisoning by strychnin. This discovery is due to the late Dr. Samuel Houghton, a distinguished Irish scientist.

Aboriginal Therapeutics of Tobacco.—The present general (and widely diffused) employment of tobacco as a social solace, and its particular (and comparatively limited) use as a therapeutic agent, receive a somewhat weird illumination from a perusal of a booklet bearing the title "A Counterblast to Tobacco," published under the name and seal of the famous English monarch, James I. The opening paragraphs of this forcible document contain the following sentences:

That the manifold abuses of this vile custome of tobacco taking may be the better espied, it is fit that first you enter into consideration both of the first originall therof, and likewise of the reasons of the first entry thereof into this country. . . . For tobacco being a common herbe, which (though vnder diuerse names) growes almost euerywhere, was first found out by some of the barbarous Indians to be a preservative or antidote against the pocks, a filthy disease, whereunto these barbarous people are (as all men know) very much subject, what through the vncleanly and adust constitution of their bodies, and what through the intemperate heate of their climate: so that as from them was first brought into Christendome that most detestable disease; so from them likewise was brought this vse of tobacco as a stinking and vnsauourie antidote for so corrupted and execrable a maladie, the stinking suffumigation whereof they yet vse against that disease, making so one canker or venime to eate oute another. And now, good countrymen, let vs (I pray you) consider, what honour or policy can moue vs to imitate the barbarous and beastly manners of the wilde, godlesse, and slauish Indians, especially in so vile and stinking a custome? . . . Why doe we not as well imitate them in walking naked as they doe, in preferring glasses, feathers, and such toys, to gold and precious stones as they doe? Yea, why doe we not denie God and adore the diuel, as they doe? . . . It was neither brought in by king, great conquerour, nor learned doctour of phisicke. . . . For if they that first put it in practise here had remembered for what respect it was vsed by them from whence it came, I am sure they would haue bene loath to haue taken so farre the imputation of that disease vpon them as they did, by vsing the cure thereof: For *Sanis non est opus medico* and counterpoisons are neuer used but where poison is thought to preceede.

A Physiologic Indictment against Tobacco.—The latest report that we have received from the Old World of special importance in relation to the influence of the use of tobacco on the human economy is decidedly against its reputation. It represents the promiscuous employment of "the weed" as antagonistic to the survival of the human race. The cigarette has been brought up in scientific custody, charged by Dr. Le Tuge de Segrais, of Luchon, with the infliction upon its too confiding devotees, of the physiologic mutilation of impotence. The prosecution was opened in the pages of the *Archives Générales de Médecine*, and the charge has been further maintained by the corroborative testimony of Dr. Georges Petit, who conducted experiments on a number of conspicuously philoprogenitive animals—dogs, cocks,

rabbits, and guineapigs—by the various methods of inhalation (of smoke) of gastric injections, and of rectal enemas. Sclerotic changes were induced by such procedures, in the testes and ovaries, respectively, of the animals subjected to experiment. Coming from the chosen land of dwindling population and decreasing families, such information deserves special attention. And in this connection, it is interesting to note that in the quaint and rare volume published by the French explorer, André Thevet, who went (in 1555) to America with the object of taking part in the foundation of a French colony near the mouth of the Rio Janeiro, there is special mention made of the anti-aphrodisiac properties of tobacco. In "*Les Singularités de la France Antartique, autrement nommé Amérique, et de plusieurs Terres et Isles découvertes de nostre temps*," a quarto dear to the heart of the bibliomaniac, and bearing the date 1558, this observant traveler tells us that "the women in America forbore the taking of tobacco, because that they have been taught that it will hinder conception and bodily lust" (Parkinson's paraphrase). What physiologist, even in the twentieth century, can be absolutely confident that he has made an undeniably original discovery!

REVIEW OF LITERATURE

Marmorek's Antituberculous Serum.—Klein and Jacobson¹ report the case of a man of 31 with tuberculosis of the left apex. He had several hemorrhages and tubercle bacilli were found in his sputum. The left lung presented in front impaired resonance to third rib, diminution of the respiratory murmur and rales above and below the clavicle; behind, the same signs and prolonged expiration. Over the right lung in front and behind, impaired resonance and deficiency of the respiratory murmur were noted, but no rales. During the next two and a half months he was given 13 subcutaneous injections of Marmorek's antituberculous serum; in all 120 cc. were absorbed. A second examination showed the condition of the lungs to be: Left lung, impaired resonance in subclavicular fossa, normal respiratory rhythm, slightly diminished vesicular murmur with a very few rales below the clavicle; right lung normal. The patient had increased 25 pounds in weight; the cough, etc., had disappeared; the general health seemed good. No tubercle bacilli in expectoration. The patient's condition continued very good. A patient of Neele's with phthisis florida was treated with antituberculous and antistreptococcic serum, receiving 720 cc. of the former in 45 injections and 200 cc. of the latter in 13 injections, with the result of apparent complete recovery. All the symptoms disappeared, as did the tubercle bacilli, and the lungs cleared up almost entirely. [E.L.]

Congenital Narrowness of the Pylorus a Cause of Chronic Gastric Disease in the Adult.—A. Ernest Maylard² says there exists a class of patients in young adult life who owe their chronic gastric trouble to a congenital narrowness of the pylorus, and that the proper treatment under such circumstances is gastrojejunostomy. He reports seven cases in which he successfully performed this operation with splendid results. In regard to symptoms, he states there is nothing pathognomonic, but the usual ones are obstinate gastric symptoms not to be accounted for and any of the usually recognized causes. The patients are mostly women in young adult life and rather below the normal stature and build. A feature of importance is that these patients are nearly always greatly improved by dieting, but with a certain return of the abnormal condition when the diet ceases. In some instances the diet offers such relief that operation is not indicated, but in most of these cases the condition is one of semiinvalidism at best, and operation would, in the long run, be much more satisfactory to the patient. Relief may be more or less immediate, but it often takes months to effect a cure. The stomach having been deranged for years it can not be expected to be completely relieved in a short time. Posterior gastrojejunostomy is the operation of choice. [A.B.C.]

Immunization against Tuberculosis.—From a turtle which had perished from spontaneous pulmonary tuberculo-

sis, F. F. Friedmann¹ succeeded in cultivating a variety of tubercle bacilli which when injected into guineapigs made them immune against large doses of human tubercle bacilli. Any of the animals treated with these turtle bacilli reacted with a local infiltration which resolved itself within a short time and upon killing them a short time later, no trace of tuberculosis was found. Control animals treated with human bacilli develop the disease typically and upon autopsy are found to have the disease in every organ and tubercle bacilli abound in large numbers. Immunized animals develop a soft tumor at the point of inoculation which ruptures after a few days, discharges some purulent matter and then heals up. The animals continue to thrive until killed; autopsy reveals no disease whatsoever, excepting isolated very minute gray nodules, which are, however, not tubercles but accumulations of round cells; they do not contain tubercle bacilli. Similar nodules were described by Koch, Neufeld and Behring in immunized animals. He has also succeeded in immunizing turtles against the turtle tubercle bacilli by first injecting them with tubercle bacilli of warm-blooded animals. The author is now working with the immunization of other animals and as guineapigs are the most susceptible of all to the tubercle bacilli of other species, he is certain that he has discovered a means by which he is able to protect all species against tuberculosis. [E.L.]

Late Effects of Typhoid Fever on the Heart and Vessels.—W. S. Thayer² gives the results of a study of the cardiac and vascular complications and sequels in 183 cases of typhoid fever treated in the clinic of Dr. Osler during the past 14 years. He found that the average systolic blood-pressure in these old typhoids was appreciably higher than in control observations upon healthy individuals, this being constant in every decade. The radial arteries were palpable in a proportion nearly three times as great as in supposedly healthy individuals who never had the disease. The average size of the heart was greater than in the same cases at the time of admission to the hospital. Nearly a fourth of the cases in which during the attack, systolic apical murmurs were detected, showed, on later examination, evidences of organic heart disease. Thayer states that the number of cases is too small to justify final conclusions, but the results tend to support the view of those who regard typhoid fever as an active element in the etiology of a considerable number of cases of cardiac hypertrophy and dilation coming on sometimes in early life, as well as an important factor in the production of certain vascular changes. [A.G.E.]

Functional Kidney Diagnosis without Catheterizing the Ureters.—To determine the functional ability of the kidneys without having to catheterize the ureters, F. Voelcker and E. Joseph³ have injected indigo-carmin into animals, and have watched the work of the individual kidneys through the cystoscope. They chose indigo-carmin because it is excreted exclusively by the urine, is nontoxic even in large doses, and passes unchanged through the body, differing in these respects from methylene-blue. Their method consisted in dissolving 0.4 gm. of the stain in 10 cc. normal salt solution, warming it and injecting 4 cc. of this solution into the gluteal muscle. Within 20 minutes it begins to be excreted, reaching its maximum very shortly, and continuing for a matter of 10 hours. The urine is deeply colored throughout the elimination of the staining substance and the working power of each kidney can be watched through the cystoscope with ease. Unilateral disturbances can be recognized by the variations from the normal rhythm of discharge. Several cases are related in which the superiority of this test over all others is shown. [E.L.]

Acute Copper Poisoning.—E. Schaeffer⁴ reports the case of a baby of three days, which was murdered by means of a copper salt. The postmortem findings were: Tongue and gums bluish in color, icterus, numerous hemorrhages in the muscles, heart, lungs, thymus gland, gastric and intestinal mucosa, kidneys and liver; fatty and albuminous degeneration of liver, kidney, heart and temporal muscle; inflammation of stomach and intestines; a large ulcer above the iliocecal valve;

the blood and blood clots contained a finely granular precipitate (copperhemol). Chemic examination of a small piece of liver revealed the presence of 5 mgr. of copper. The violent intestinal inflammation indicated excretions of a large portion of the copper; the liver seemed to act as storage house for the copper. [E.L.]

Congenital Hypertrophic Stenosis of the Pylorus.—Edmund Cantley¹ says, that this affection is not uncommon is proved by the number of cases recorded. In a paper read in 1898 he reported 20 cases as having been collected from the literature, including his own. In 1902 the total number had exceeded 50. The recognition of the condition is most important, since operative treatment has proved curative, while in the absence of such recognition and treatment prognosis is practically hopeless. In the present paper he reports an additional case, in which, however, the symptoms did not point to this condition, but the postmortem examination showed the pylorus stenosed by benign enlargement. In the last five cases, exclusive of the one mentioned, which have come under his observation, he has been able to palpate a small tumor in the region of the pylorus, and in four of these life was saved by pyloroplasty. He is of opinion that marasmus seen in infancy is caused by benign stenosis of the pylorus, which can easily be remedied by operation, if the patient's vitality is not too far reduced. [A.B.C.]

Dilation of the Esophagus without Stenosis of the Cardiac Orifice.—A patient of Kelling's² had diphtheria with paralysis of the soft palate five years before her death. Ever since this time she experienced difficulty in swallowing. She often vomited without nausea. Four years later at the age of 68, she began to vomit food eaten one to two days previously. She died one year later of inanition and cardiac weakness. Examination of the esophagus showed a spindle-shaped dilation immediately above the diaphragm. The cardiac orifice was not contracted. A histologic examination of the esophageal structures showed the cause of the dilation to be an atrophy of the longitudinal bundles of muscle fibers which in this case evidently depended upon degeneration of pneumogastric fibers the result of the diphtheric paralysis, but any infectious or metabolic disease leading to a degeneration of nerves may produce a similar condition. Such a condition leads to a disappearance of hydrochloric acid from the stomach, which therefore is of symptomatic importance. The condition is incurable and is best treated through the introduction of an apparatus. Other interesting cases similar in etiology and effect are cited. [E.L.]

Acute Septic Colitis Due to Milk Poisoning.—G. F. Vincent³ reports the case. A man of 32 complained of cutting pains in his neck, the left shoulder, of swollen cervical glands, furred tongue, occasional attacks of slight jaundice, and persistent diarrhea; there was abdominal pain without any constant definite location, a practically normal temperature but with a pulse running well above 100. The patient gradually grew worse, becoming emaciated, the diarrhea failed to yield to treatment and the vomiting constant. The patient died. A necropsy showed the cecum, ascending colon and proximal half of the transverse colon enormously distended and of purplish color. The intestine macroscopically was edematous, soft and spongy while the internal surface was covered with minute gas bubbles. The pathologic examination established the septic nature of the disease and Vincent concludes that it was clearly due to a contaminated milk-supply, which the medical health officer found to be the cause of a then prevailing epidemic of sore throat. The patient was supplied with milk from one of two dairies contaminated and to within a few days of his death he drank freely of this milk. [A.B.C.]

Investigations Concerning Human Actinomycosis.—From extensive investigations with actinomycosis hominis, K. Doepstein⁴ formulates the following conclusions among others: The ray fungus grows on all nutrient media, but especially well in glycerin agar at body temperature; slower and scantier growth at room temperature; whether aerobic or anaerobic does not matter. It forms superficial, yellowish colonies with slightly depressed center, from which radiations pass out.

Gelatin liquefies slowly; bouillon becomes clouded. The development of the fungus from the spore is described as follows: The granules become longer and divide; the paired structure grows at its points, the threads becoming longer and longer; they become connected by branches after several days and ultimately break up into little rods through segmentation. The fungus stains by Gram's method before and after it divides, but not while it breaks up. The rods are sometimes club-shaped, due to granules within them; after their expulsion they were again rod-shaped. The actinomyces from fresh pus is stiff and longer, its threads fit over the end like a cap and it does not stain with Gram. The fungus was discovered by the author in the contents of decayed teeth; this adds to the plausibility of dental instruments being the carriers of the disease, and makes their sterilization after use an absolute necessity. [E.L.]

Congenital Bronchiectasis Associated with Situs Inversus.—Siewert¹ reports a case having a history of a cough since birth. Until the patient was 10 years old the cough was accompanied by vomiting, after that time vomiting ceased. The cough is productive, the sputum is free from elastic fibers and tubercle bacilli; upon standing it separates into 3 layers. Just above and below the left clavicle a tympanitic note, cracked-pot sound, and amphoric breathing are obtained. The heart-beat is on the right side in the fifth intercostal space; liver dulness absent on the right, but present on the left side; stomach and spleen are on the right side. [J.F.]

Absorption of Nutrient Enemas Containing Peptone and Peptone-alcohol.—To determine the relative value of the varieties of nutrient enemas mentioned above, A. Bial² experimented upon himself. For two days he dieted himself in such a manner as to produce well-formed soft stools. On the third day, after thorough cleansing of the bowel, three portions of a 10% watery peptone solution were injected at intervals of seven hours. Two weeks later a similar experiment was made with enemas containing 10% peptone and 10% alcohol. Chemic examination of the stools evacuated after each of the experiments revealed that of the pure peptone enema, 50.5% of the peptone was absorbed, while of the peptone-alcohol enema, 66.01% of the peptone was taken up. The nutritive value of the latter is 475 calories greater than of the former, an amount which must be considered of great value in an individual suffering from inanition. [E.L.]

Dietetics of Diabetics.—Sir James Sawyer³ recounts that the researches of Mossé have radically changed his views with reference to the dietetics of this class of patients. Mossé proved that potatoes, instead of being harmful as was commonly supposed, form a useful and beneficial food in glycosuria; that they are capable of being substituted for ordinary wheaten bread in daily proportions sufficient to maintain the elementary ratio, that is, in the proportion of 2 lbs. to 3 lbs. of potatoes for 1 lb. of bread. He found that a daily ingestion of from 1,000 gm. to 1,500 gm. (2 lbs. or 3 lbs.) brought about, in 19 cases out of 20 cases of diabetics, speedy diminution of the glycosuria, quick relief of thirst, general improvement of the patient; this holding true in all forms of diabetes. The salts contained in the potato are chiefly potassium and to the increased amount of this salt in potatoes is attributed the superiority of this vegetable in diabetic dietary. Sawyer, after investigation, agrees entirely with Mossé, but advises strictly that the potatoes be cooked by steaming with the skin on, that the potassium salts shall be retained. He goes even farther and advises that a meal may be made of the ground-up potato and skin and a bread be made from this for diabetics. He reports excellent results from the use of such bread. [A.B.C.]

Tuberculosis of the Peritoneum.—C. Thoenes⁴ has collected 244 cases of tuberculous peritonitis, which were operated upon by different surgeons; of 186 cases with a serous exudate 114 (61.3%) were cured; of 55 cases with adhesions 18 (30.6%) recovered completely. Comparing the surgical results with those of the clinician, it is noted at once that the surgeon gets only the worst cases to treat, the medical man keeping all the lighter ones for himself. In spite of this the actual figures of

¹ The Lancet, March 5, 1904.

³ British Medical Journal, March 5, 1904.

⁴ Münchener medizinische Wochenschrift, Vol. I, No. 50.

the surgically treated cases are better than those of the medical cases; the surgeon cured 54.7% of his 244, the medical man only 48.2% of his 82. [E.L.]

Experimental Syphilis.—E. Metchnikoff and E. Roux¹ inoculated a young female chimpanzee with syphilitic virus; 25 days later a typical hard chancre appeared; the inguinal lymph-glands of the same side enlarged. A month later papules developed on different parts of the body which remained until the death of the animal 14 weeks after the primary inoculation. Death was due to a generalized pneumococcal infection. They inoculated a 5-year-old male chimpanzee with fluid from the chancre and one of the papules of the first animal. Chancres appeared in both places and the corresponding gland enlarged within 35 days; no secondary lesions appeared, nor were syphilitic changes found at the autopsy. [E.L.]

Distribution of *Bacillus Coli Communis*.—J. H. W. Eyre,² carrying out a research along the lines followed in the Fourth Report of the Royal Commission on Sewage Disposal, has found that *Bacillus coli* may be isolated from the intestinal canal of the small rodents, such as the mouse, rat, guinea pig, the rabbit, and also the cat and dog. Likewise from the sheep, the goat, horse, and the cow. Specimens of the common fowl, such as the duck, the pigeon, sparrow, killed and examined immediately, all yield abundant evidence of *Bacillus coli* in the alimentary canal. Kern has demonstrated the presence of this bacillus in the intestinal tracts of birds of prey. The author has made special investigation in reference to fish and finds that fish taken from off the Lincolnshire coast, such as the sprat, the smelt, mullet, etc., all carefully examined, showed *Bacillus coli* in the intestinal tract. The contention is not warranted that these results point to the presence of this bacillus as a normal inhabitant of the intestinal canal of fish in general, but at least opens the subject to further investigation, and we may find that this bacillus is synonymous with sewage contamination. [A.B.C.]

The Influence of Röntgen Rays on Animals.—H. Heineke³ exposed a number of white mice to the action of Röntgen rays for intervals varying between 5 hours and 19 hours. All of the animals died in from 6 days to 10 days. Symptoms of disease appeared 1 day to 2 days before death; they consisted of rapid emaciation, refusal of food, tremor, conjunctivitis, diarrhea and coma. The greater number of guinea pigs thus treated died also, the interval varying between 7 days to 15 days. Death occurred no matter whether the whole body was treated, only the head or only the body; in the latter instance the brain was protected by thick layers of lead foil. Postmortem examinations showed all the organs to be normal with the exception of the spleen which was dark brown in color, small and shrunken; this shows death to have been due to destruction of red blood cells. [E.L.]

GENERAL SURGERY

MARTIN B. TINKER

A. B. CRAIG

C. A. ORR

REVIEW OF LITERATURE

Cirrhosis of the Stomach.—John G. Sheldon⁴ reports that a male patient of 52 had suffered for years from a series of symptoms which, except for the time element, resembled closely the indication of malignant disease. Laparotomy was performed, the stomach was found normal in shape, but very small. It measured 15 cm. (6 in.) in its greatest length, and 5 cm. (2 in.) in its greatest diameter, the external surface was smooth, and there were no adhesions. Gastroenterostomy was performed with a Murphy button, the stomach wall was at least 1 cm. in thickness, and fibrous; the gastric mucosa was smooth and atrophic. The button was passed on the thirteenth day; the patient has made a complete recovery. Though vomiting was persistent and frequently threatened the patient's life before operation there has been no recurrence of this trouble since the operation. All annoying symptoms have subsided, and the patient at the time of writing had gained 36 pounds.

The author then reports a series of cases collected from literature, which he reports in some detail. The treatment of the condition is surgical. Patients will not die until the pylorus is nearly closed, and they literally starve to death. The operation drains the chronic inflamed stomach and thus permits rehabilitation. [A.B.C.]

Abduction Position in the Treatment of Affections of the Shoulder-joint.—M. Schueller¹ pleads in all cases of injury about the shoulder-joint, whether fractures, dislocations, sprains or operations, for abduction of this joint and the arm during after-treatment, instead of the time-honored fixation to chest by means of plaster-of-paris, Desault, and Velpeau bandage. With the arm tied to the chest, the future functioning power of the arm will be very much interfered with. With the position recommended by him, fixation and immobilization are as easily brought about and future use of the joint is not endangered, as the adhesions formed in this position can be stretched readily during passive movements. He shows illustrations of an apparatus which is comfortable for the patient, as well as efficient for the purpose, and reports the details of several cases in which it was used. The result was especially brilliant in a case of old dislocation of the shoulder-joint, in which the arm was absolutely immobile. He discusses rules governing the length of time in which the arm is kept in this position. It differs with each type of lesion and the result which is desired. When passive movements are commenced, external motions should precede anterior and posterior abduction, and abduction movements should be the last. [E.L.]

The Treatment of Penetrating Wounds of the Abdomen.—M. L. Harris² reports a series of 16 cases, and concludes as follows: (1) In penetrating wounds of the abdomen there are absolutely no known symptoms which indicate injury to any of the viscera, except those of the urinary tract, stomach, and occasionally the lower bowel; (2) except those relating to shock, all symptoms following such wounds indicate either internal hemorrhage or peritonitis; (3) to wait for symptoms of perforation of the intestines means to wait until peritonitis has developed; (4) every bullet or stab wound which penetrates the abdominal cavity should be operated upon at the earliest possible moment in order to anticipate peritonitis; (5) no time should be wasted in attempting to demonstrate the presence or absence of intestinal perforation by rectal insufflation of gases or the analysis of recollected intraperitoneally injected air or liquids; (6) it is essential to systematically examine the entire gastrointestinal canal regardless of the point of entrance of the wounding body; (7) when the alimentary canal has been perforated suitable drains should be placed either through the operative incision or counter incision as may appear best suited to the particular case. [A.B.C.]

Successful Treatment of an Inoperable Sarcoma with Röntgen Rays.—J. G. Chrysopathos³ operated on a woman who had a large, rapidly growing tumor of the right ovarian region; finding it to be a sarcoma, a diagnosis which was confirmed by microscopic examination, he began to treat it with Röntgen rays. She was treated two to three times weekly, and after about eight months was discharged cured to all intents and purposes. Neither abdominal nor vaginal examination offered the slightest abnormality. She is now treated about once every two to three weeks, and has been well for some months. [E.L.]

Enormous Prostatic Calculus.—G. Frank Lydston⁴ reports that a farmer of 34 was fallen upon by a horse and the perineum sustained a severe blow. Hematuria followed, with out obstruction of the urethra, and he was apparently well within 10 days. Six months later there was difficulty of micturition, he passed several small calculi, and has done so at intervals since. Examination revealed a calculous structure at the bulbo membranous junction, and enlargement of the prostate. Operation was advised, and through a perineal incision a calculus weighing 720 grains was removed from the prostate. Lydston believes that as a consequence of the traumatic stricture a certain quantity of residual urine continually remained

² Annals of Surgery, March, 1904.

³ Münchener medizinische Wochenschrift, I, 50.

in the canal, decomposition followed, with the formation of secondary calculi. The obstruction caused dilation of the prostatic ducts, small secondary calculi were forced into the latter, and one of these became enlarged, forming a nucleus about which was deposited the material which resulted in the formation of the large stone. [A.B.C.]

Fibromas of the Tunica Vaginalis.—Edward A. Balloch¹ reports that a colored male of 16 presented himself with a much elongated scrotum. There were found three separate masses on the right side of the scrotum. A diagnosis of fibrous growth of the tunica vaginalis was made, operation was performed and all the growths were enucleated without difficulty and the redundant skin of the scrotum was removed. Healing was without unusual event. His conclusions are that irritation is an important factor in the production of the fibroma of the tunica vaginalis; that they spring originally from the subserous connective tissue, but may become detached and let loose in the cavity; that they are mostly of the variety known as soft fibroma; that they are prone to myxomatous and fatty degeneration; that the testicle may be affected by the same form of degeneration; that the growths are generally minute; that excision is the only effectual remedy; and that since the testicle on the affected side is liable to become involved the propriety of removing it should be considered. [A.B.C.]

Talma's Operation and its Results.—B. S. Koslowski² considers this operation perfectly rational in hepatic cirrhosis, where it assists nature in establishing a collateral circulation. Experience has shown, however, that in order to be successful the operation must be performed in the earlier stages of cirrhosis, before the liver-cells have lost their functions beyond restoration. Hence we must operate during the hypertrophic stage of cirrhosis. Advanced hepatic atrophy is a contraindication. So is general debility, cardiac disease, renal involvement, and icterus. The various methods of attacking the omentum do not seem to influence the outcome. The operation is not more difficult or dangerous than exploratory laparotomy. From a series of 168 cases the author finds the percentage of favorable results (cures and improvements) to be 46, that of unfavorable results, 49 (4% unknown). The most encouraging outcome was seen in early operations, when we can expect 50% of successful cases. The operation removes the ascites, while its effect on the process in the liver is not as yet definitely known. [L.J.]

Treatment of Fracture of the Base of the Skull.—Capt. Robert E. Bell³ reports in some detail the histories and treatment of four patients suffering from fracture of the base of the skull. That which he makes emphatic is his conviction that operation should be performed more frequently in these cases than is commonly practised. He believes that fractures of the middle fossa, with escape of the brain tissue from external auditory meatus with cerebrospinal fluid, or the latter alone, should not be treated symptomatically, but rather that they should be operated upon. The day of ice-bags and rest in bed only for fractures of the base have passed. In all cases of fracture of the base, unless we have some positive indication that we will hasten death by interference, we should resort to artificial respiration, if necessary, and open the skull, determining by the symptoms and the findings the seat of lesion, stop the hemorrhage, remove clots, establish drainage, and irrigate with plenty of hot salt solution. Only with such treatment can the best results be hoped for. [A.B.C.]

Radical Operation for the Cure of Cancer of the Pylorus.—William J. Mayo¹ believes that cancer frequently develops upon an old ulcer scar. In about 60% of cases the pylorus is the seat of origin, and in 70% of cases it is involved. Cuneo demonstrated that the fundus and two-thirds of the greater curvature are free from lymphatic involvement in cancer of the pylorus. Acting on this suggestion, Mayo's operative procedure involves the ligation of the four principal arteries supplying the pyloric portion of the stomach. He then ligates the gastrohepatic omentum in sections along the lesser curvature to near the cardia; then proceeding along the greater curvature, he ligates along the pylorus as far toward the cardia

as it is designed to go with the operation. The duodenum is doubly clamped and divided with the actual cautery to prevent inoculation of the cut surfaces with cancer. The duodenal stump is closed; a long Kocher clamp is placed at the left extremity of the ligated gastrohepatic omentum in oblique direction so as to save as much as possible of the greater curvature; the clamping plates are covered with rubber tubing and only sufficient force to retain the tissue in the grasp is used. A second clamp is applied to the tumor side to prevent leakage between the two; the tissues are severed with the cautery a quarter inch from the Kocher clamp and the pyloric end is thus removed; the cauterized stump is sutured with a catgut button-hole continuous suture from above to the lower extremity and retraced and tied. The whole is reinforced with a Cushing right-angled suture and a separate gastroenterostomy is performed at the most dependent portion of the stomach. In this procedure not nearly so much of the stomach is sacrificed as in a previous method advocated by Mayo. [A.B.C.]

Surgical Treatment of Gastropexy.—After reviewing a considerable portion of the literature of the subject, Hammer,¹ concludes that gastroenterostomy is the best operation for the greater number of cases. The greater number of the symptoms of gastropexy appear at the time when the stomach is full—that is, at the height of the digestion act, and the chief indication therefore is a rapid evacuation of the stomach, and the removal of the food from the stomach into the intestines; a gastroenterostomy will do this quicker than other operations. Gastropexy not only does not aid the emptying of the stomach materially, but as it produces adhesions to the surrounding organs, also leads to the production of new symptoms and complications. The permanent results from gastropexy have, if anything, been poorer than those of nephropexy. Stomach operations should be performed oftener however, especially in cases where medical treatment relieves the patient only so long as it is followed out and where the patient is too poor to give himself the care which such a condition requires. [E.L.]

Early Radical Treatment of Inguinal Adenitis.—Richard L. Sutton,² Surgeon, U. S. A., recommends operative treatment for obstinate painful enlargements due to infection by the gonococcus or occurring as sequels of chancroidal lesions; treatment is not directed to bubo in its entirety. He recommends the radical removal of the enlarged glands, under aseptic precautions, claiming that by so doing the period of convalescence and inability is rendered much less in extent, and the patient thereby being relieved of a long period of tentative treatment. He has operated recently on 10 patients after the manner suggested and as a rule, in 7 days or 8 days, the patients were all discharged and ready to be placed on duty. A general anesthetic is given, the operation is slight, and the disability trivial. The dressings employed when pus was present were of plain sterile gauze, the first layer applied loosely over the wound and securely covered in with aseptic pads, cotton and a spica bandage of the groin. Daily irrigations of hot, saturated solution of boracic acid were used, and gauze packing and drainage instituted from the first. [A.B.C.]

The Surgery of Perforating Gastric Ulcer.—Archibald MacLaren³ believes that many of those cases can be diagnosed promptly if the cardinal symptoms are remembered and recognized. The secret of success in the treatment is in operation at the earliest possible moment followed by suture of the opening with silk or linen. The peritoneum should be sponged, if little soiled, and the wound closed without drainage. But if considerable fluid has escaped into the peritoneal cavity a large-sized drain should be put into the pelvis through a stab wound over the symphysis and the patient placed in the reversed Trendelenburg position. He reports in detail three cases under the following captions: Perforating latent gastric ulcer on the anterior wall, operation 11 hours after perforation, recovery; probable perforating gastric ulcer, death in 29 hours without operation or postmortem; subacute perforating gastric ulcer, operation nine hours after perforation, recovery. He believes perforating gastric ulcer occurs more frequently than is commonly supposed. [A.B.C.]

GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

REVIEW OF LITERATURE

A New Method of Uterine Suspension for Retrodeviation.—N. Bardescu¹ describes a new procedure for the relief of retrodeviation which he has employed in a number of cases with entirely satisfactory results. The operation consists of 2 parts: 1. Treatment of the lesion and reduction of the malposition. 2. Suspension of the uterus by a displacement of the round ligaments. After curetment, which is important, an abdominal incision is made in the median line, the intestines are protected by sterilized gauze compress; the condition of adnexa is examined, adhesions broken up, the deviation reduced and the organ attached to the anterior abdominal wall. Then a button-hole like opening is made in the abdominal wall on either side of the incision about 2 cm. to 3 cm. from the edge of the wound. Through the openings, with small forceps, the round ligaments are drawn and fastened in this position by means of catgut sutures, 2 on each side, which serve not only to hold in position this exterior loop of the round ligament, but also to reduce the size of the buttonhole opening. After suturing the peritoneum, then the rectus muscle with the aponeurosis, the exterior loops of the round ligaments are brought into contact and fastened together with 3 sutures. The operation is then completed by suturing the skin so that the lower half will be attached to the aponeurosis. [W.K.]

Angioma of the Breast.—P. Malapert and R. Morichau-Beauchant² report in detail a case of this affection, and present notes on 13 from the literature. Their patient was a girl of 12; her parents had noticed a swelling in the right breast 15 days after birth. This growth began to extend when the girl was 5 or 6 years old. When operated upon the tumor was the size of a small orange. One large and two small cysts, containing a serosanguineous fluid, were within the mass. Histologic study showed the tumor to be an angioma. It had developed in the fibroadipose stroma of the breast; the acini and ducts of the breast; in the regions not invaded by the growth, still persisted. The tumor was not encapsulated. The cysts were apparently due to regressive changes. In addition to their own case, the writers find 9 undoubted cases in the literature, 4 of those reported being considered as doubtful or as belonging to a different type of tumor. They divide angiomas into cutaneous, subcutaneous, or glandular. Of the 5 cases of the last type, 2 were in males, 2 in females, and 1 the sex not given. The other types are more frequent in males. The tumors exist either from birth or the first few months of life. The diagnosis is ordinarily very easy. The treatment of the cutaneous nevi is that of those growths anywhere; that of the subcutaneous angiomas is excision if the breast is not involved. If the gland is involved, the treatment should be that of the glandular type, which is entire removal of the breast; in this way only can recurrence be prevented. [A.G.E.]

A Double Vagina with Single Uterus.—F. Marchand³ thinks that of all forms of malformation which result from defective union of Müller's ducts, the double vagina with single uterus is the rarest. These ducts uniting throughout into one, form the normal uterus and vagina. According to Nagel's investigations, the upper or proximal ends of the ducts are formed of cylindric cells, and the lower or distal ends of large cells rich in protoplasm. The union of the proximal ends and the persistent separation of the distal ones, form a single uterus with double vagina as in the case reported by Marchand. A virgin of 22, dying of brain tumor, it was found at the subsequent section that a normally formed uterus was connected with a twofold vagina into each division of which a finger could be introduced. The external orifice of the uterus opened toward the left of the septum which here deviated somewhat toward the right. The vulva showed two distinct vaginal openings, at each of which appeared a hymen. [W.K.]

Complication of Pregnancy with Appendicitis.—A. Labhardt⁴ reports two cases of complication of pregnancy with

appendicitis, but of entirely different type. In the first case there was an abortion in the early months of pregnancy and immediately following appendicitis, with formation of an abscess. Since the patient had been suffering for some time with pain in the right ileocecal region he believes the appendicitis was the cause of the abortion. As the temperature continued rising after emptying the uterus, an abscess was opened on both sides of the abdomen, but in the bad condition of the patient no direct search was made for the appendix. Her condition now improved somewhat, but as the temperature continued abnormal, a vaginal examination showed an abscess in the Douglas sac, which was also opened, and the patient ultimately recovered. In the second case, the appendicitis followed a normal delivery and there was recovery without operation. Labhardt concludes from his experience and study of the subject that there is no reason to think that pregnancy has given rise to appendicitis but that, when of a severe type, the latter may induce abortion; and that in general the influence of appendicitis upon pregnancy is most unfavorable. But pregnancy may have this influence: Through the hyperemia of the pelvic organs an absorption of the inflammatory processes takes place and thus a natural condition acts as a therapeutic measure. [W.K.]

Dermoid Cyst of both Ovaries.—C. F. Adams¹ reports this case which occurred in a young woman of 26. Menstruation began at 14 and was regular, the flow being scanty and accompanied by pain the first day. The principal complaint of the patient was extreme nervousness and at times some pain referable to the right iliac region, more marked at the menstrual period. Operation showed the left ovary to be large as a horse chestnut, the right considerably larger. The left contained sebaceous material and teeth, some of them almost perfectly formed; the right contained sebaceous material and hair. The patient made an uneventful recovery. Dermoid cyst of both ovaries is considered by the writer to be of sufficient rarity to be worthy of note. [A.G.E.]

Five Successful Hysterectomies in One Family.—J. McPherson Lawrie² reports a remarkable example of fibroid disease occurring in one family, for a family of 9 sisters furnished 5 examples of fibroid disease with 5 successful hysterectomies. In this connection he discusses the question of heredity but fails to reach any definite conclusion. Some authors compute that 4 women in every 10 have fibroids. If this proportion is correct, 5 cases out of 9 does not seem remarkable enough to be considered as evidence of heredity. [W.K.]

Foreign Bodies in the Abdominal Cavity.—F. v. Neugebauer³ reports 87 cases of foreign bodies left in the abdomen by operators, including forceps, scissors, and sponges. He quotes the remark of R. E. Weir that he considers it almost impossible to guard against this contingency absolutely. We can only by great care reduce them to a minimum. Neugebauer is convinced that one chief cause of such accidents is imperfect or bad anesthesia, leading to interruption or hasty conclusion of operation. Hence the necessity for an experienced anesthetizer. Another safeguard is such a position of the patient as gives the best command of the operative field by eye and hand. Another important matter is a sufficient illumination of the field of operation, and a careful personal assistant. Then a multiplicity of instruments should be avoided, and forceps, scissors, sponges, etc., so arranged that the loss of any would be instantly noticed. Have the hemostatic forceps in a hand glass, and needles and ligatures in a special plate. [W.K.]

Chronic Metritis and Endometritis.—W. E. Fothergill⁴ reviews some of the recent writings on these so-called conditions, with special reference to their relation to the life-history of the uterine muscle. The works of several writers, who have endeavored to elucidate the pathology of numerous conditions that are still named "endometritis" and "metritis," though noninfective in origin, are considered at some length. The investigations of Theilhaber, Meier, and Donald are interpreted as certainly proving the existence of a noninflammatory condition, in which the main symptoms are discomfort, menorrhagia,

¹ Zentralblatt für Gynäkologie, January 23, 1901.² Revue de Chirurgie, February 10, 1901.³ Zentralblatt für Gynäkologie, February 13, 1901.⁴ Münchener medizinische Wochenschrift, February 9, 1904.¹ The Postgraduate, January, 1904.² Brit. Med. Jour., February 13, 1904.³ Zentralblatt für Gynäkologie, January 23, 1901.⁴ The Practitioner, March, 1904.

and leukorrhea, and the most obvious pathologic feature is hypertrophy of the uterine mucosa. Fothergill says it must be allowed, even if the conclusions of these observers are not accepted as final, that the uterine muscle plays a greater part in the causation of common pelvic disorders than has hitherto been recognized. The application of names ending in "itis" to conditions of noninflammatory origin is not in accordance with the spirit of modern pathology. The terms endometritis and metritis should be reserved for infective cases. [A.G.E.]

A Detached Head in the Parametrium.—C. Weber¹ reports the case of a woman, aged 25, who had an abortion in the fourth month. The fetus was born without the head, which had been torn off and could not be found in the uterus. Although no laceration could be felt in the uterus, which was empty, a laparotomy was decided upon, and there was found between the folds of the broad ligament a small sized tumor, the detached head. [W.K.]

Influence of Narrow Pelvis on Weight of the Child.—S. S. Kholmogoroff² has compared two series of cases, 1,000 each, in order to find the influence of the pelvis on the infant's weight and length. He makes the following generalizations: 1. Children born of mothers with narrow pelvis weigh less than those born of normal women. 2. The length of the first group is also less than the length of the second. 3. With successive pregnancies the infant's weight in cases of narrow pelvis tends toward increase. 4. The number of boys is comparatively larger in cases with narrow pelvis than in normal ones. [L.J.]

TREATMENT

REVIEW OF LITERATURE

Red Light Treatment of Smallpox.—J. T. C. Nash³ reports red light treatment in some 30 cases of smallpox. Though none of the cases were necessarily fatal by ordinary treatment, the author believes that the suppurative stage was considerably modified and rendered less severe and dangerous by the beneficial influence of the red rays, or rather by the exclusion of the other elements of light. Insufficient experience with this means of treatment, he believes, has led a number to condemn and abandon it, when a more extensive experience might have led to different views. The results obtained must of necessity depend very much on the malignancy of the disease and the type of the epidemic. Prior vaccination, of course, plays the principal role in lessening the virulence of the disease, but the author is of opinion that his experience fully justifies him in the belief that the red light is of distinct benefit. One disadvantage of the red light ward is that the physical appearance of the smallpox eruption can not be appreciated or demonstrated as by ordinary light. [A.B.C.]

Treatment of Gastritis.—Achilles Rose⁴ makes several postulates regarding conditions of the stomach; among the more important are the following: Erosions of the stomach, in most instances, are of no clinical importance; washing out of the stomach has been overdone; olive oil introduced into the stomach has proved of great value in pyloric stenosis; chronic gastritis is often associated with atonia gastrica, and symptoms which are in reality due to gastropnoia are sometimes attributed to gastritis; when gastropnoia and nervous symptoms exist, the gastropnoia should first be relieved; atonic gastritis merits more attention than it has thus far received. The best means to relieve this condition is strapping the abdomen with adhesive plaster; strapping is well tolerated by most persons and answers much better than bandages, the latter being absolutely useless in lean persons. For the medical treatment of gastritis proper, Rose knows only one remedy—a powder composed of equal parts of bismuth subnitrate and calcined magnesina. The dose is one even teaspoonful in water, a half hour before each meal. [A.G.E.]

Treatment of the Tuberculous at Fort Stanton, N. M.—Paul N. Carrington,¹ Surgeon United States Public Health and Marine-Hospital Service, gives a summary of the work accomplished during the year ended April 30, 1903. The altitude of Stanton is 6,150 feet, the average mean temperature was 53.6° and the precipitation varies from 14 in. to 17 in. annually. During the year in question there were treated 282 patients, of whom only 39, or 15%, were in the first stage, which latter is defined as one in which the disease has not progressed to consolidation, but which may be detected by physical signs. The second and third stages are those in which the physical signs reveal consolidation, with or without excavation. Of those patients in the first stage, 50% have recovered and 37.5% discharged improved; of the second and third stages, only 5.6% recovered and 51% were discharged improved; 7.3% were discharged unimproved. Of the entire number treated during the year, 24.9% died; 2.8% remained unimproved; 54.2% improved, and 18.1% apparently recovered. The essentials of the treatment are abundance of fresh air, liberal diet and rest. The author emphasizes that rest is very important. The observations of Carrington are all the more interesting since he himself has been cured of pulmonary tuberculosis by his residence at Stanton. [A.B.C.]

Tetanus Treated by Injections of Antitoxin into the Spinal Theca.—Wallace and Sargent² report four cases in some detail. The antitoxin in each instance was injected into the spinal theca, there being little doubt, they assert, that the lumbar injection is preferable to the intracranial. Of the four patients they saw the incubation periods were respectively three, six, nine, and eleven days; two may be considered acute and two subacute or chronic; three of the patients recovered; the fatal case being subacute in character. The amount of the antitetanic serum used at each injection was 10 cc., and the total amount varied in the different cases according to its apparent effect upon the symptoms. Combined with the antitoxin, chloral and the bromids were used in some instances. While the effects of the treatment are not conclusive, the authors are of the opinion that the intrathecal injections are fully warranted. [A.B.C.]

The Medical Treatment of Neuralgia and Myalgia.—In two patients, Ernst Meyer³ was able by the administration of hydrochinon, to relieve pain that yielded to nothing else, even morphin giving transitory relief only. He began with 1 gm. and gradually increased to 4 gm. daily. The drug was taken just before going to bed. Meyer often observed profuse perspiration upon the neuralgic extremity after ingestion of the drug, and once he noted increased frequency of the pulse and vertigo. [J.F.]

Treatment of Hemoglobinuric Fever.—H. Hearsey,⁴ medical officer in British Central Africa, reports that it was the custom, until recently, to treat the numerous cases of hemoglobinuric fever in his district with large doses of quinin, as much as 60 grains daily being given in many instances. During three years of this treatment the mortality was estimated at 33½%; death from suppression of urine was the termination in the great majority of fatal cases. This unsatisfactory result led Hearsey to adopt a different method, and he reports 18 consecutive cases of hemoglobinuric fever treated with sodium bicarbonate and solution of mercuric chlorid (mercuric chlorid and ammonium chlorid, ten grains each to one pint of distilled water) in doses of 10 gr. of the former to 30 m. of the latter. There was not a single death in the series. The combined action of the two drugs being antacid, diuretic and disinfectant to the gastrointestinal tract, vomiting is allayed and diuresis freely established. No case of suppression of urine occurred. The mixture is given every two hours for the first 24 hours, and subsequently every three hours until the urine is free from hemoglobin. No ill effect was noted in any case, notwithstanding that in four instances there were relapses and the treatment had to be repeated. The diet consisted of milk and barley water given frequently in addition to the ordinary liquid and semisolid diets. [A.B.C.]

PUBLISHED WEEKLY AT 1321 WALNUT STREET PHILADELPHIA BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. VII, No. 18.

APRIL 30, 1904.

\$5.00 YEARLY.

Schools in vice and crime would be a proper designation of many of our jails, almshouses, and prisons. One reporter concerning the conditions found says, that in nearly every jail groups of men gathered around benches or tables were engaged in card playing. They spend their days in this manner; they gamble for everything they possess, except the clothing that covers them. Fully a third of the men seen were under 25 years of age; about a fifth were under 21 years of age. Bedding goes unwashed, walls and cells unpainted, and an army of idle men spend their days in vice. Place the most innocent young man in the world in the average county jail, his cell so dark that he cannot see to read in it; give him a dirty bed, a germ-infested blanket, and force him to pass months without exercise or employment, in the company of gamblers, felons, and vagrants, and if he does not become one of them it will be the greatest miracle ever wrought. It is certainly inconsistent with all reason to permit the means of punishment for one vice or crime to become the means of education in all the others. Almost unanimously, the jail officials protested against such conditions. Why has the legal profession permitted such a disgusting and expensive system of criminal breeding to grow up under its protection, and without a word of protest? Its function should have been to prevent, not multiply crimes.

Women in Jails.—"The conditions found in many jails," says Miss Alice L. Woodbridge, a New York prison visitor, "might have existed in the dark ages." A report of the State of New York inspection says that in the majority of the jails, women come directly and solely under the care of men. In jails where there are no toilet accommodations the women inmates, under the eye of the jailer, march daily to the cesspool with their night buckets. No one can expect a woman to retain any sense of decency or modesty under such circumstances; no one can expect a jailer to perform such duties and retain any respect for his prisoner or himself. The wife of one sheriff stated that she had known a woman to be five months in jail and never see the face of another woman. These women are searched by men and cared for by men. When I asked one sheriff, who searched the women prisoners, his face grew crimson as he replied: 'I do; I am ashamed to acknowledge it, but I assure you it is very little searching they get.' Several sheriffs

stated that they never searched women prisoners. When asked how they ascertained if these women had drugs or liquor in their possession, the reply was that they could tell after a few days by the appearance of the women. Fully one-third of the women seen were awaiting trial and had been in jail for months. Only four jails have provisions for the separation of those held for trial, or as witnesses, from those serving sentence; and women of all classes, innocent and guilty, young and old, are in constant association. Where is the legal profession, and where is its conscience?

The medieval torture-chamber still exists, if we may judge from the reports as to the "sweat-box" and the "third degree." What the concealed infamy of the last may be is difficult to learn. The "sweat-box" is a method of confining suspects in heated air until the torture becomes so irritating as to elicit almost any confession desired, especially when coupled with cunning questions and probings of the prosecutors. But where is the boasted trial by jury and by his fellows of the Anglo-Saxon love of justice? It has been supposed, wrongly it seems, that a man is held to be innocent until his crime has been proved by orderly and just trial. Punishment should not therefore begin until after conviction. The poor degenerates at best are poor matches for the subtle and astute questioners without the added perplexity resulting from torture. Why not revive the rack and screw and be done with them quicker and without trial? Will some one tell the simple truth about the abuses of the so-called examinations of prisoners before trial? What exactly is the proceeding in the "third-degree" torture business? By what law are such things allowed and what have the judges and lawyers been about to permit such barbaric anachronisms in the twentieth century?

The enforced idleness of prisoners is a cruelty, both to the tax-payer and to the prisoner. In the last report of Allegheny, Pa., County workhouse, for instance, there is a daily average of more than 300 men in the prison who have nothing to do. An hour of exercise in the court-yard in the morning, another in the afternoon, constitute their only employment. These are able-bodied men, able and willing to work, who ought to be earning their living instead of being compulsory wards living at public expense. Ill health, mental depression,

morbid brooding over troubles, habits of idleness acquired, irritable chafing over real or imagined wrongs, occupy the solitary hours of the narrow cells. In such a condition there is no response to either mental or moral teaching, and retrograde rather than progressive results follow a term of imprisonment under these conditions. Under the present restricted law, it is impossible to devise any employment which will give work to all the prisoners. The Prison Association of New York says the fact that the tax-payers of the counties are compelled to support in idleness several thousand able-bodied prisoners is a frightful anomaly of our government; yet even this is of slight moment compared with the moral and physical evils which arise from keeping prisoners in enforced idleness. Referring to the thousands in penitentiaries and county jails, the report adds:

Here is an inert mass of humanity forcibly removed from society and maintained like a stagnant pool in a corrupting miasma of inactivity, as if the only object of such an institution were to breed the scum civilization and to propagate it in the community. For it must not be forgotten that the most of these men in the course of six or nine months are going out of prison worse than when they came in.

The immediate amendment of the law as to competitive industries in prisons, almshouses, etc., is demanded. And the State control of prisons and jails is almost as important.

Reforms in prisons and jails, reforms of almost all kinds, and almost everywhere, judging from the reports, is the demand of the hour. It is the shame of the legal profession, which must have long known and winked at the horrors now exhibited. The county jails are often in a most disgusting condition, filthy, cold, the prisoners provided or not provided with food and clothing, herded together worse than animals, the old criminals contaminating the young with the worst moral and physical diseases, and every abuse tolerated which greed could devise and indifference permit. The sheriffs are allowed a profit on the provisions, etc., furnished, and of course they frequently cheat the prisoners of the legal allowances and commands. Enforced idleness is common—the result of the stupid and criminal socialism of the labor voter. Of the conditions, *e. g.*, in Illinois, the Secretary of the Board of State Commissioners of Public Charities, says:

Gloomy, unsanitary, dingy, unhealthful, and cheerless, they strike not at the criminal instinct and mental disorder, but at the physical well-being of their victims. Many of the county jails of Illinois are positively bad, unfit even for temporary occupancy. They are built with the sole view to confine prisoners and prevent their escape. No thought of comfort, cleanliness, sanitation, exercise, encouragement, or education was taken into account. Very few of them afford any relief from constant and enforced idleness. There is no opportunity either for mental or physical development. Rarely do we find here any separate provision or facilities for the care of sick or insane prisoners. Oftentimes the buildings are extremely cold in winter and suffocating in summer. Little or no fire protection is afforded.

The Herter Lectures.—An event of unusual importance took place in Baltimore April 12, 13, and 14, when Professor Paul Ehrlich, of Frankford-on-the-Main, upon invitation of the medical faculty of the Johns

Hopkins University, delivered the first series of Herter lectures, founded by Dr. and Mrs. Christian A. Herter, of New York. It was a source of extreme satisfaction to Professor Ehrlich, as well as to the faculty of the Johns Hopkins University, that, despite the intricacies of the subject and the fact that the lectures were to be delivered in the German language, over 800 persons assembled to hear the first lecture. The three lectures were devoted to a discussion of (1) The mutual relations between toxin and antitoxin; (2) physical chemistry versus biology in the doctrines of immunity; and (3) cytotoxins and cytotoxic immunity. Professor Ehrlich discussed at length his now wellknown side-chain theory, and, pointing out the complexity of apparently simple functions, devoted considerable time to an elucidation of his conception of the duplex action of toxins, of the haptophore and the toxophore groups of bodies. His second lecture was devoted largely to his polemic with Arrhenius (and others) who, on physicochemic grounds, have criticised adversely his side-chain theory and his conception of the duality of toxic constituents. It was quite natural that his third lecture, in which he discussed bacteriolysins, agglutinins, and cystolysins, should in some respects attract the most attention, since these subjects are at present so extensively the object of scientific inquiry. It is impossible here to discuss adequately a subject of which the newness and intricacies are so great that a veritable new language has had to be invented with which to clothe the thoughts of the masters, but it is significant of the probable developments of the future that Professor Ehrlich believes that antitoxins of higher potentiality will yet be discovered. He directed especial attention to the important fact that the immunity reaction is reduced by too highly toxic treatment of the experimental animals, and that progress in the production of curative serums is to be expected only when it becomes possible to obtain antitoxins of greater avidity than those now produced. He believes that the selection of particularly favorable animal species and the use of toxins of least avidity or ultratoxones will, most probably, bring this problem much nearer its final solution. Aside from the value of the lectures as contributions to medical literature, they assume especial importance as a strong link in the scientific chain that binds kindred spirits across the seas, and there is much cause for congratulation that an event so happily inspired by Dr. Herter should have been brought to a successful issue by those to whom it was entrusted.

The conditions and occupations of the blind, especially of the State of New York, is the subject of a valuable report of a committee to the Legislature which has just been issued. From it one learns of the spirit and practical measures at work to better the condition of these unfortunates, and particularly to make them self-supporting. The committee has done a great and useful work with rare unselfishness, its chief aim being to encourage the acquirement of an industrial trade on the part of the adult blind. There are about 6,000 blind persons in New York State, 9.72% under 21 years of age, 53.14% over 60, and 22.88% between 21 and 50; 960 cases were personally investigated. The blind, of

course, are generally poor, and as financially speaking their self-support is generally a failure, charity in some form or other supplies the means of their living. The city of New York, the city of Cleveland, and the State of Illinois give a certain sum in pensions to the blind and needy citizens. Beside this there are four private homes in New York City, supporting about 150 inmates. Connecticut has an excellent industrial training school, California and Iowa industrial homes, Indiana a workshop, and other States, numbering in all eleven, have undertaken some movement toward the same end. We notice among the interesting occupations pursued by the blind is that of massage, long ago recommended by Dr. Bennett. One blind man runs a buzz-saw.

The conclusions and recommendations as to the blind by the committee of New York are as follows:

Conclusions.

At least 65% of the blind are too old to acquire and to follow any industrial occupation, while another and unknown proportion of them are physically or mentally unsound.

In the case of many who are sound, long enforced idleness has destroyed the desire to work, so that it would require time to overcome the indolence to which they have become habituated.

Most of the blind, especially among the women, do not travel far alone, and hence they must reside near their work or it must be carried to them.

The adult blind of the Greater New York are apparently better situated than those of the rest of the State, and they do not therefore evince any particular desire for State assistance.

Many of the blind, especially of the women, are for the most part comfortably cared for in the homes either of relatives or of friends. It would seem unwise under such conditions to cultivate the "institutional habit" by segregating those thus situated, in homes especially provided for the blind.

Extended experience in Great Britain and the United States seems to indicate that "workshops," for adult blind men at least who are of working age, are generally far more successful than are "industrial homes."

A few of the adult blind, even under existing conditions, become wholly or partially self-supporting.

While the product of their labor would probably be of sufficient value to afford the blind a comfortable support, the time consumed in selling this product prevents them in reality from gaining such support.

Adults and children should not be trained in the same institution or under the same management. Some form of manual training for boys should take the place of the industrial training now conducted in schools for the young blind.

All attempts to combine industry and charity in the same establishment and under the same management have proved in every instance to be at best financial failures, and such must continue to be the case since by this combination a premium is put upon idleness by giving the most charity to the least industrious person.

While the giving of pensions is the simplest method of aiding those who seem to require financial assistance, it is in a very large number of instances not only an unwise method but is demoralizing in its effect upon the recipients.

With all the deductions that have been previously made there are still very many adult blind men and women who are capable of being taught and of following some industrial trade for whom suitable provisions should be made.

Recommendations.

1. We recommend that the work of personal visitation begun by this Commission shall be carried on and completed.

2. That provision be made for the industrial training of the blind over 21 years of age—and to that end that in the city of Buffalo there be established tentatively, in a rented building, one industrial training school or "school-shop," and that as

soon as possible manual training replace the industries now followed in the State School for the Blind.

3. Such modification of existing laws as will enable the blind to sell their products to State and municipal institutions.

4. Measures should be taken to determine the causes of existing blindness, and that such preventive measures be employed as will tend to lessen future blindness in the State.

5. To carry out the foregoing recommendations we finally recommend that there shall be established a permanent Commission.

Camphor: Mostly a Japanese Product.—One of the inevitable results of the present Russo-Japanese conflict will be to lower the supply (and raise the price) of the familiar drug, camphor, throughout the rest of the world. The special nursery of camphor is the group of islands which form the Japanese Empire, and some of the neighboring ones. The source of the camphor of Japan is a majestic tree, *Laurus* or *Cinnamomum camphora*. It is obtained from the root and branches, which are heated in iron vessels surmounted by hemispheric domes, in which it condenses after sublimation. The chemic formula of camphor is $C_{10}H_{16}O$; it is chemically classed with the aldehydes; and forms one of the group of stearoptenes. The physical characteristics of this substance are too familiar to require detailed description. It is met with in masses of apparently crystalline form; of pronounced odor, and of hot and bitter taste; it is moderately friable; volatilizes readily at ordinary temperatures; is but slightly soluble in water (1 to 870); but is readily soluble in alcohol, ether, and oils. There is also a "camphor of Borneo," which is chemically an alcohol, and is obtained from the *Dryobalanops camphora*.

The physiologic and therapeutic effects attributed to camphor are numerous, and are worthy of special study. It has long been regarded as an antiseptic. It destroys the microorganisms of disease and also the leukocytes, but its effects are very transitory. Its action on the cutaneous surface is that of a stimulant; it may even produce inflammation, if the skin is delicate; and, of course, produces this effect more readily on a mucous or an ulcerated surface—or that of a wound. It is rapidly absorbed by the gastrointestinal mucous membrane; and to some extent even by the skin. The introduction of camphor into the circulation causes a temporary increase of the proportion of leukocytes. This has been attributed to vasodilation in the abdominal viscera. At the same time, by its paralyzing effects on the white corpuscles, it diminishes leukocytic diapedesis; hence its antiphlogistic action. It also exercises a pronounced antipyretic influence; it was specially recommended in fevers by Huncher, more than a century ago (*De igne per ignem extinguendo, sen de præstantissimo camphoræ usu in febribus acutis*, Wittenberg, 1792.) Taken by the mouth it produces acceleration of the pulse, a generalized sensation of heat, and a general stimulation of the vascular and nervous systems. It also produces increased energy of the contractions of the cardiac walls, and increased velocity of the current of blood. In large doses, it causes psychic exaltation, and an immediate desire for movement; this is followed by a feeling of lassitude and prostration. There is a corresponding

effect on the heart; excessive activity, followed by tendency to paralysis. When excessive doses are taken, convulsions of clonic type have been known to result followed by paralysis. Camphor appears to be eliminated, as such, by the skin; and of the urine in form of camphoglycuronic acid ($C_{26}H_{54}O_8 + H_2O$) of which there have been recognized 2 varieties, α and β . In this respect its course is allied to that of benzol, phenol, thymol, chloral, resorcin, hydroquinon, etc. In the department of urinalysis it is important to bear in mind that it is a potent reducer of cupric oxid.

The therapeutic uses of camphor are of considerable number and variety. Its antiseptic properties are seldom referred to now, but in the days before Lister it was found of great benefit in the local and constitutional treatment of hospital gangrene and erysipelas. It has also been administered with the same view in cases of intestinal disease. Camphor has an old-time reputation for relieving toothache, when a morsel is introduced into the external auditory canal. It is taken in the mouth for the same purpose—in the solid form or in solution. Its antipyretic action—although well defined—is seldom heard of now. Its chief reputation in Europe has for a considerable time been that of a diffusible stimulant. The German physicians employed it very extensively for some time in way of hypodermic injection (solution in oil). Camphorated lavements were employed in cases of adynamic typhoid fever. Like many other diffusible stimulants, it acts, in sufficient doses, as an antispasmodic; and the combined or alternate exercise of these qualities will best explain its reputation in bronchitis and asthma. Its action on the skin is well known to be stimulating, an effect to which its volatility probably contributes. All such applications necessarily render latent a large quantity of the surface heat, and thereby stimulate the coats of the bloodvessels. Its known power of arresting diapedesis also aids in forming a scientific foundation for its reputation as an antiphlogistic and an antilactic. Its oftmentioned aphrodisiac and anaphrodisiac effects, in small and large doses respectively, have probably no better foundation than the stimulating and antispasmodic properties above referred to. Its modern fame in this department seems to be largely a traditional expansion of the celebrated Salernitan verse:

Camphora per nares castrat odore nares.

Medieval Knowledge of Camphor.—Its remote origin would appear to have thrown a kind of glamor around the reputation of camphor. To this its prompt, spontaneous volatilization, or rather sublimation, would add a considerable factor. It appears to have been introduced into European medicine in the sixth century, and the notice of it by *Ætius* made it famous at once. Its oriental circulation was that of a costly perfume, of which presents were conveyed to monarchs by the hands of ambassadors and heralds, as of "gold, frankincense, and myrrh." The total knowledge of the drug available in England in 1640 was collected by the famous herbalist, John Parkinson, and may be read with profit in the twentieth century—as affording a gratifying example of the expansion of knowledge in this interval:

Camphora: Camfire.—Camfire, called *caphura* from the Arabians' *cafar*, is such a subtle thing, both in substance and nature, that although it is the gum or liquor of a great vast tree (like to a walnut tree, whose wood is somewhat solid and firme, and of an ash colour like unto beech, or somewhat blacker, the leaves are whitish like unto willow leaves, but neither flower or fruite have been observed, yet is likely to beare both), partly distilling forth of its owne accord, but chiefly by incision, which commeth forth cleare and white, and hath no spot therein but what it acquireth from their foule hands that touch it, yet what we have and use seemeth plainly to be so made by art, being cast as it were, or sublimed, into broad round pannes or dishes, and little about the thickness of one's thumbe, cleere, white, and transparent, but not to be made into powther of itselfe (although it is somewhat brittle, and will breake into many small peeces) without the helpe of a blanched Allmond, or some other such like unctuous thing, which hereby will reduce it into fine powther: neither will it be easily dissolved in cold water, but by warmth will be resolved like unto fat, being easily set on fire, and will burne in the water, serving for wild fire with the other things, and is of a very strong, fiercesent, both sent and substance vanishing away, if it be exposed for a while to the open aire; yet the wood being made into severall workes, will smell thereof a long time: Some take it to be hot, because it is of such tenacity of parts. *Rhasis* saith it is cold and moist, but *Avicena* saith it is cold and dry, and that it causeth watchings and wakefulness, and quieteth the senses of those that are hot, which are contrary one to the other, as *Garcias*, and *Scaliger* upon *Garcias* noteth it. Camfire doth coole the heate of the liver and backe, and all hot inflammations and distempers of heate in any place of the body, easing the paines in the head, and restraining fluxes, either of blood out of the head and nostrils, being applied to the forehead with the juyce of Houseleake or with Plantaine water, and some Nettle seed, for the fluxe of sperme in man or woman, using it to the veines or privy parts, and extinguisheth Venery, or the lust of the body: It is a preserver from putrefaction, and therefore is put into divers compositions and antidotes to resist venome, poysons, and infection of the plague or other diseases: it is good in wounds and ulcers to restraints the heate, and is of much use with women that desire to preserve their beauty, by adding a luster to the skinne.—[*Theatrum Botanicum*, p. 1575.]

Disease Reported among the Japanese.—According to the reports of spies, the Japanese troops in Korea have been ravished by various diseases. One of these diseases, called "imbion," is a kind of intermittent typhus. Another, called "souda," which has not yet been studied by European doctors, produces premature senility. The patients lose their teeth, become extremely weak, and the nails are twisted back on the fingers.

Pure Food and Alcohol.—Information from Washington states that the friends of the pure food bill have abandoned all hope of having it passed at this session. Most of them think that there is small likelihood of the measure getting through next year. The general opinion seems to be that the whisky interests have killed it, because provision is made in the bill prohibiting the sale of certain kinds of adulterated liquors. The bill to prohibit the sale of adulterated foods was passed a few weeks ago in the house, and in due time was reported by the Senate committee. It is now on the calendar, but everything is against getting further along the legislative route.

Leprosy Cured?—In a lecture recently delivered in New Orleans, Dr. Dyer, physician of the Lepers' Home of Louisiana, after saying that there were 3,000,000 lepers in existence, or one to every 500 living persons, announced it is reported that in the last two years the problem of curing this dread disease had been solved. In 10 years, Dr. Dyer is reported as having said that he and his assistants had succeeded in removing every trace of the disease in 12 lepers. In the past two years, since the latter part of 1902, every case at the Louisiana Leper Home, except those in the very last stages of the disease, had been improved materially, and in three cases the lepers are almost well, and it will be possible to discharge them within a comparatively short time. Treatment means a perseverance for years, not for weeks or months. Dr. Dyer expressed confidence that if the treatment of leprosy was begun early enough and maintained long enough, that the disease could be cured as easily as any other. In another decade, he said, it will be universally recognized that leprosy is as curable as typhoid or yellow fever.

AMERICAN NEWS AND NOTES

GENERAL.

Bequests to Charity.—By the will of the late George Huster Gardner, of Philadelphia, the sum of \$15,000 was left to various Roman Catholic charities in the city of Philadelphia. The following hospitals were remembered: St. Mary's Hospital, St. Joseph's Hospital, St. Agnes' Hospital, each the sum of \$1,000.

Would Mail Microbes to Farmers.—At the Patent Office recently a patent was issued and dedicated to the people of the United States. It covers a process discovered by Dr. George T. Moore, of the Department of Agriculture, for the production of bacterial cultures employed in inoculating soils for the successful cultivation of clovers of all kinds, alfalfa, soy beans, cow peas, and many other similar members of the legume family. The patent is given to the people of the United States forever in effect, the object being to forestall any effort to patent such a process and by that means circumscribe the efforts of farmers to improve their soils by raising leguminous crops. The department has for several months been sending out in small packages through the mails the necessary bacteria dried on cotton and accompanied by nutrient salts, with which the farmers may inoculate either the soil or the seed which is to be sown in the soil.

Increase of Suicide in the United States.—According to statistics presented in an article by George P. Upton, of Chicago, the number of cases of suicide is rapidly increasing in the United States. This shows that in the past 13 years 77,617 people have committed suicide in this country, an average of nearly 6,000 per annum. In 1902, 50 cities furnished 2,500 cases out of a total of 8,132 occurring throughout the country: in 1891 the number of suicides was 3,531; in 1895, 5,759; and in 1903, 8,597. Of the 77,617 suicides, 57,217 were males and 20,400 were females. The greatest ratio of increase is noticed among women under 25 years of age. It is noted also that the suicides among children have increased to a considerable extent. It is further noted that during the 13 years there were 41 suicides among physicians, which is more than the number of suicides of those belonging to any other profession. Previous to 1894 most of the suicides were committed by the use of firearms, usually the revolver; since that time most of the deaths have resulted from various poisons, carbolic acid being most frequently used.

A Scientist's Declaration that We Eat too Much.—A paper read before the National Academy of Sciences recently, described a series of experiments recently conducted by the Sheffield Scientific School of Yale to determine if the average human being is not eating too much. Prof. Russell H. Chittenden, the director of the school, who conducted the experiments, declared that the average healthy man eats from two to three times as much as he needs to keep him in perfect physical and mental health and vigor. The subjects of the experiment were professors, students and United States soldiers. There was a gradual reduction of meat and other proteid foods, with little, if any, increase in starch and other foods, but in only one case was meat entirely eliminated from the diet. At the end of the experiments, covering periods of from six months to nearly a year, all the men were in the best of health. Their weight in some cases was almost exactly the same as when they began, and in some slightly lower. Their bodily vigor was greater and their strength was much greater, partially owing to their regular physical exercise during the experiments and partially owing, Professor Chittenden believes, to the less amount of food eaten.

Adulterated Foods.—In a recent address, Dr. Harvey W. Wiley, Chief of the Bureau of Chemistry, at Washington, D. C., is quoted with the following statement: In Washington nearly every one thinks he uses Java or Mocha, or a mixture of those coffees. The fact, as shown by the figures of the Treasury Department, is that there are only about 3,000,000 pounds of those coffees imported into the country. Nearly all of this is on private orders, and hardly a pound ever gets into the market. Eighty percent of the 800,000,000 pounds of coffee sold under those names come from Brazil. It costs from 4 cents to 11 cents a pound, and is sold under the false name at from 35 to 40 cents. He showed the coloring used in giving food products, what the manufacturers call natural colors. These articles are all coal-tar dyes. Yellow butter contains such coloring matter, and sauces—especially catsups, invariably contain them. The cherries used in making cocktails are a purely artificial product. The natural cherry is first bleached, soaked in brine until all the substance, except the skin and the cells of the tissue, is destroyed. They are then filled with glucose, made with sulfuric acid, containing some arsenic, and coloring matter made from coal-tar. In many cases, dyes contain arsenic. Arsenic is a cumulative poison, and long-continued use of it in exceedingly small doses results in arsenical poisoning. This happened in England 2 years ago, when there was an epidemic of arsenical poisoning from drinking beer. Pure

wine vinegar, according to the label, was found to be made from the poorest kind of spirits. Jams, jellies, and preserves are made from apple parings and cores, with chemic flavoring and coloring.

Statement by Professor August Forel.—The following communication is forwarded us for publication: "From August, 1879, until March, 1898, I was the director of the Burghölzli Insane Asylum and professor of psychiatry at the University of Zurich, and desire to make the following statement: Dr. Carl Bertuhringer, who has designated me as a representative of the so-called König Medicine Company, of Chicago, and who incidentally represents himself as a former assistant of Professor Forel at the Burghölzli Asylum, was never my assistant and never an assistant at the Burghölzli Asylum. He did, indeed study medicine in Zurich, and, like other students, study psychiatry with me, and practised in the clinic as a so-called 'practikant,' as did other students. Under these circumstances I once permitted him to hypnotize one patient. But he was never either my asylum nor my private assistant, and hence has no right to publish himself as such. Another Dr. Bertuhringer (not Dr. Hans Bertuhringer) was actually assistant physician in Burghölzli, and is now second physician at the Rheinan Asylum, Canton, Zurich. But this is quite another person. (Signed) Dr. August Forel (former professor at the University of Zurich.) Chiguy, Switzerland, April 6, 1904."

Commend the Faithful Physician.—The *Public Ledger* recently announced that two New York physicians attached to the staff of Bellevue Hospital had contracted tuberculosis as a result of their faithful attention to the unfortunate patients entrusted to their care, and referred to the fact that some 18 more Bellevue internes are known to have become victims through labors among the tuberculous applicants for aid at that hospital. The previous announcement, however, did not record, nor will any future number be called upon to notice, any resignations from the Bellevue staff of physicians, nor any lack of young medical men willing to take up the work of those who fall its victims. It is only one fact of many illustrative of the heroism of the medical profession. The doctor's devotion to duty, his willingness to sacrifice himself to others and his habitual disregard of personal comfort and safety are not so picturesque as the loyalty, the unselfishness, the bravery, of the soldier in the field, but they are of infinitely more human advantage, and of heroic quality no less to be admired. The physician does not march into the presence of danger enthused by the sound of martial music, allured by the advance of his country's flag, comforted by the touch of his comrades' shoulders, certain of the applause of the world. His adventure is prosaic and lonely. Only in the appreciation of the thoughtfulness is its heroism considered.—[*Public Ledger*, Philadelphia.]

Miscellaneous.—**New York:** Dr. Simon Flexner, director of the Rockefeller Institute, has been elected president of the American Association of Pathologists and Bacteriologists. Dr. Addison W. Baird is the author of a leaflet on tuberculosis, addressed to the public, which has been accepted by the A. I. C. P., which will distribute 10,000 copies to the public. The senior class of the New York College of Physicians and Surgeons has given a loving cup to Professor George M. Lefferts, who has been made professor emeritus by the trustees of Columbia University, after a long career as professor of laryngology at the Vanderbilt clinic. Another loving cup was presented to Dr. Lefferts by his clinical assistants on the occasion of his recent farewell address. Dr. Lefferts has been teaching laryngology for 30 years.—**Porto Rico:** The Legislature of Porto Rico has appropriated the sum of \$5,000 to defray the expenses of an investigation into the prevalence of ankylostomiasis in the island. The investigation is to be conducted by Captain Ashford, of the Military Hospital.—**Washington:** Dr. J. C. Simpson, second assistant physician at the Government Hospital for the Insane, Washington, D. C., has sent in his resignation, to take effect May 16. Accepting Dr. Simpson's resignation, Secretary Hitchcock paid a high tribute to the retiring physician, and extended the thanks of the Department of the Interior for his long and efficient services.—**Boston:** "Dr. Nichols, of Boston, alleges," says *The American Inventor*, "that cocaine is used to stimulate football players. 'Besides enormous doses of strychnin, cocaine is known to be employed by professionals in athletic games. I have unquestioned evidence that in the last Harvard game one of the eleven was drugged to force his supreme effort.'"
—**Chicago:** At a recent meeting of the stockholders of the Chicago Eye, Ear, Nose, and Throat College, the following directors for the ensuing year were elected: Drs. W. A. Fisher, A. G. Wipperfurth, H. W. Woodruff, J. R. Hoffman, and Thomas Faith.—**Baltimore:** Professor H. C. Jones, of the Johns Hopkins University, has received a grant of \$1,000 from the Carnegie Institution for research in physical chemistry during the year 1904-1905.—**Archives of Electrology and Radiology.**—The number for March, 1904, appears under the new editorial management, the editor being Dr. Clarence Howard Skinner, of New Haven, Conn. It is promised that an endeavor will be made to develop the journal so as to cover its proper field as comprehensively as possible. The issue in question contains valuable reading matter and is thoroughly up to date.

NEW YORK.

For the Relief of Bellevue Physicians.—It has been announced that steps were being taken to ameliorate the condition of the Bellevue physicians as soon as possible. The top floor of the old Bellevue College Building, has been renovated, and will be partitioned off into dormitories for the doctors. When that is done there will be only two or three doctors in a room instead of four or five as at present.

The Sale of Cocain in New York State.—Pharmacists of New York state, that since the State law prohibiting the sale of cocain except on prescription went into effect, the drug has dropped just about \$1 per ounce in price. The general demand for it has ceased altogether, and the pharmacists sell only to physicians. Of course, it does not follow that the doctors do not dole it out to patients. Cocain used to cost druggists \$6 an ounce; then it dropped to \$5.50. Now it is selling at \$4.25.

Would Exterminate Germs by Fumigating all Public Buildings.—In the opinion of Health Commissioner Thomas Darlington, every home in New York where there has been a case of grip should be fumigated by the formaldehyde process, just as it would be for a case of scarlet fever or diphtheria. The Commissioner believes it would be a wise thing if, under the present extraordinary conditions of the public health, churches should be thoroughly and scientifically disinfected between each Sunday service, schools after each day's session, theaters every day before the matinee or evening performance, and cars used on the overcrowded surface and elevated lines at least once in every 24 hours.

The Optometry and Osteopathy Bills Defeated.—Much credit is due from the profession in general, and from its members in New York State in particular, to Dr. Frank Van Fleet, chairman of the committee on legislation of the Medical Society of the State of New York and his coworkers, in their successful fight against the optometry bill and the osteopathy bill, whose advocates strenuously sought to have them enacted into law. It is stated that no such persistent and concentrated effort has ever been made in the State of New York for legislation detrimental to the profession, and those who succeeded in defeating the measure had to labor strenuously and persistently. To the credit of many legislators be it said, however, that they were anxious to learn the opinion of the profession in general in the State with reference to the measures advocated, and once having the matter clearly before them there was little hesitancy in their placing their influence on the proper side.

The Proposed New Bellevue Hospital.—Details about the new Bellevue Hospital that is to be built were made public a few days ago, and they show that for the next 10 years, if the plans of the architects are approved, the city of New York will be building in instalments the finest hospital in the world. The cost of the enormous structure, containing 12 pavilions and embodying all the appropriate improvements of modern science, will be \$11,000,000. The new hospital, in which nearly 3,000 patients may be treated, will cover almost all the available space from Twenty-sixth to Twenty-ninth streets. Over the entire building will be a roof garden, to which many elevators will run. No ward will be without its elevator. At certain points on the roof will be glass inclosed sections, where weaker patients may be sheltered, and yet out of doors. Fresh air, plenty of it all the time, is the main thing in a modern hospital. In no other institution anywhere has this idea been carried out as it will be in Bellevue.

Would Have Malarial Cases Reported.—According to a New York exchange, the Board of Health, having started its spring war on mosquitos, issued a statement requesting doctors to notify the department of all cases of malarial fever which come under their observation. This is the explanation. In most instances the occurrence of a case of malarial fever in a certain locality means the existence close by of a breeding place of the anopheles, and if all cases of malarial fever are reported, it will be an easy thing to investigate the surrounding locality for breeding places and stamp them out. This will not only greatly reduce the number of cases of malaria, but the spread of the disease from one part of the community to another. It is now a part of the routine work of the Department of Health to make free microscopic examinations of the blood for the malaria parasites, and any physician can have such an investigation made on request. As a safeguard against malarial fever it is interesting to know that the anopheles, unlike the culex (the ordinary nonmalarial mosquito), flies and bites only after sunset, or in extremely shady spots. For this reason, if houses are carefully screened, there is little danger of being bitten by the pests, even in a malarial community.

PHILADELPHIA, PENNSYLVANIA, ETC.

Nurses Declare in Favor of Registration.—The Graduate Nurses' Association of Pennsylvania, at its quarterly meeting recently at Wilkesbarre, devoted much time to a discussion of a proposed law for the registration of all nurses. One hundred nurses were present. Every voice was raised in favor of the law, and plans were discussed for bringing weight to bear upon the next Legislature in the effort to have it passed.

Typhoid in Philadelphia.—For the week ended April 23, a very slight decrease in typhoid, as compared with the previous week, was reported by the Bureau of Health. The aggregate for these seven days was 352. As on many previous occasions, the filtered water wards, the Twenty-first and Twenty-second, showed but few cases, seven and four respectively.

American Nurses Reach Japan.—Information from Yokohama, under date of April 22, states that the party of American volunteer nurses whose services have been accepted by the Japanese Government have arrived from Seattle. They received a hearty welcome. The party will visit Tokio for a short time, after which they will be appointed to a hospital ship.

Crusade against Unlicensed Doctors.—The County Medical Society decided recently to immediately establish a special fund to be used in the prosecution of illegal practitioners. The President of the State Board of Medical Examiners announced that there are more than 100 men practising medicine in Philadelphia without a license. The city, he said, should be purged of these fellows. He offered to donate \$25 toward a fund for obtaining evidence against them and aiding in the work of bringing them to justice. Attention was called to the fact that the County Medical Society had more than 950 members, and that \$1,000 could be raised by \$1 subscriptions. It was decided to adopt this means of obtaining the proposed fund. On motion, it was decided to appoint a committee of three physicians to aid the Coroner, District Attorney, and Director of Public Safety in obtaining evidence against and prosecuting malpractitioners in this city.

SOUTHERN STATES.

The Medical and Chirurgical Faculty of Maryland held its annual meeting, beginning Tuesday, April 26. Important addresses were delivered by Drs. Eugene F. Cordell, John B. Deaver, J. N. McCormack, Harry T. Marshall, W. T. Watson, B. W. Goldsborough, Thomas B. Fletcher, W. F. Lockwood, R. W. Wood, F. H. Baetger, T. C. Gilchrist, H. F. Cassidy, and others.

Texas Health Law Defied.—The health authorities of Mexico will pay no heed to the rules and regulations recently promulgated by Dr. George R. Tabor, Health Officer of Texas, regarding travelers entering Texas from Mexico, the Superior Board of Health in the latter country denying the right of the State of Texas to make such rules when no epidemic of yellow fever exists in Mexico. The Mexicans will take up the matter with the State Department in Washington.

Government Hospital in the South.—It is announced at the Navy Department that it is the intention of Surgeon-General Rixey to provide a large hospital for the naval station at Charleston, there being no modern hospital of the service south of Norfolk. The Surgeon-General, who has returned from his visit of inspection at Port Royal, has made some important recommendations in regard to the establishment at the place of an outdoor hospital for the treatment of tuberculous patients of the service.

Germ Distribution Checked.—From Louisville, under date of April 23, comes the following information: Prompt action by the city Health Department has prevented the installation of a carpet cleaning arrangement, which, it is claimed, would have spread many forms of disease over that portion of the city near the plant. The health officer found that a company intended to put in a huge fan which would blow the dirt, dust, and germs from the dirty carpets up to the chimney and into the outer air. The fan had not been put in, but preparations were being made for its installation. The officer notified the manager that he would not be allowed to scatter the dirt and disease germs over the city, and that some other arrangement to care for the carpets must be made.

An Epidemic Probably Prevented.—An exchange states that by a series of experiments which proved how readily deep wells and springs could experience pollution, the town of Quitman, Ga., has doubtless been saved from the danger of an epidemic of disease. In this place, the water-supply of the town is derived from wells, and in planning a sewerage system it was proposed to dispose of the public sewage by discharging through a bore hole into an underground stream. The possibility that contamination might result, however, was early suggested, and led to practical experiments being undertaken by the United States Geological Survey, and the Geological Survey of Georgia, in order to determine the matter definitely. Two tons of salt were placed in the well where it was planned to empty the sewage, and the water from the various wells which had been previously examined, especially as to their chlorin contents, was again analyzed, samples being taken at intervals during and some time after the experiment. It was found that the salt had permeated all of the wells in the town, demonstrating conclusively that disease germs could be readily communicated to the drinking water. These experiments are in line with some carried on in Europe several years ago, where it was found that bacteria, placed in certain wells, could be detected at other sources of water in the vicinity, and emphasized the importance of carefully examining and safeguarding water-supplies under all conditions.

WESTERN STATES.

Ohio Medical Law Declared Void.—In the Common Pleas Court at Sandusky, Ohio, Judge Reed has ruled that the Ohio State medical law is unconstitutional, because it limits the right to practise without the use of drugs or medicines to osteopaths, and by the rule of exclusion Eddyites are prohibited.

For 50 Years an Active Member of a Medical Society.—Physicians of Dubuque, Iowa, at a recent meeting of the Dubuque Medical Society, gave a celebration in honor of Dr. William Watson, who for 50 years has been an active member of this society. This venerable physician is a member of the American Medical Association. He is loved and revered by his colleagues of Dubuque and vicinity, and is well known throughout the Mississippi valley.

Chicago Policemen to Attend Lectures in Medicine and Law.—Five hundred policemen, a fifth of the entire number in that city, have presented themselves at the Dearborn Medical College to receive instruction in applied anatomy and surgery, as well as criminal law. After a five days' course of two hours a day, the students will be succeeded by other police in batches of 500. The instruction will be given in lectures by the college faculty, the attending staff of Samaritan Hospital, and by Assistant State's Attorneys.

Would Require Health Certificate to Wed.—"No marriage license without a physician's certificate of health attached," is the slogan of the Progressive Health Club, of Chicago, which has prepared a petition to President Roosevelt, asking his cooperation in the club's endeavor to secure the establishment of a federal bureau "to teach citizens the ideal possibilities of marriage." Federal legislation that will prevent the marriage of any person who cannot show a clean bill of health and prove that he has no chronic disease and never has been convicted of any crime also is asked.

Efficient Work by Chicago's Health Department.—The Bulletin of the Health Department for the week ended April 16, says: During the week the laboratory analyzed 851 samples of milk and cream—a record week's work. Of these, 4.7% were found to be below grade. The below-grade samples were mostly from shippers, many being found to be watered. These were condemned at the railroad platforms and either returned to the shipper or emptied into the sewer. During the week 35 restaurants were notified to comply with the sanitary regulations concerning the handling and keeping of their milk and cream. Suit was entered against 14 of these for unsanitary conditions, against six for selling milk and cream below grade and against two for mixing milk or cream with condensed milk.

Tuberculosis in San Francisco.—The deputy health officer says that the Board of Health intends passing an ordinance enforcing the attachment of bacteria-proof mouthpieces to all telephones in San Francisco. The object of this is to prevent the spread of contagious diseases. Tuberculosis is quite virulent here at the present time, and the Board intends taking all measures possible to prevent further ravages. The proprietors of the penny arcades will be asked to remove all blowing and lung-testing machines for the same reason. Janitors of the different schools throughout San Francisco will be ordered to sweep all rooms after school hours. Cleaning halls or yards during the time the buildings are occupied is bad for the lungs on account of the clouds of dust generated. The walls of all schoolrooms are to be washed down at least three times a month with an antiseptic solution.—*San Francisco Bulletin.*

Danger of Rabies.—The Bulletin of Chicago's Health Department for the week ended March 26, says: A number of rabid dogs having been killed within the last few weeks, the Department advises that the public should appreciate the importance of securing a dog that has bitten anyone and keeping him alive until it is positively known whether or not he is suffering from rabies. Postmortem examinations or animal inoculations do not always demonstrate the presence of rabies, especially in its early stages. It is best to secure the dog and watch him for a few days. If he has rabies he will usually die within a week or so. It is easy then to state positively that the disease is rabies or not. In New York a law passed in 1902 requires all dogs that appear to be suffering from rabies, or that have bitten anyone, to be kept under observation for 10 days. If one is bitten by a dog, whether the animal is known to be rabid or not, the Pasteur treatment should be begun immediately, because although symptoms may develop in 3 or 4 days, 6 weeks is the usual time. If the dog does not die of rabies within 10 days, it will not be necessary to continue and no harm will have been done, because this treatment is absolutely harmless. The present law requiring the muzzling of all dogs, during the entire year, is one that should be strictly enforced, as shown by the English success in exterminating rabies and by the Berlin experience. No case of rabies has been known in the German capital since 1873, when a law was passed requiring the compulsory muzzling of all dogs during the entire year.

FOREIGN NEWS AND NOTES

GENERAL.

Miscellaneous.—Dr. J. N. Langley, F.R.S., professor of physiology at Cambridge University, has been given the degree of doctor of laws by St. Andrew's University. —Professor J. H. van't Hoff has placed at the disposal of *Zeitschrift für Physikalische Chemie* the sum of \$300 for prizes for papers on the literature of the phenomena of catalysis. The papers may be published in the journal and must be received before June 30, 1905.

Chinese and the Plague.—The susceptibility of the Chinaman to the plague is proved by the fact that China and Mesopotamia were the two great world centers of the disease before India became infected. For the past 40 years plague has been endemic in the mountains of Yunnan, and there was a virulent outbreak there in 1871-1873. In 1894 there was a severe epidemic in Canton, which is said to have caused 100,000 deaths, and spread in the same year to Hongkong. It is from Hongkong that the infection is said to have spread to Bombay, which was just catching Calcutta at the time in the race to be premier port in India. Since then Calcutta has gone ahead, and Bombay has hopelessly receded, owing to seven years of plague.—[*London Chronicle.*]

Disease an Ally of Firearms in War.—An exchange, commenting on the excessive deathrate among soldiers from various forms of illness rather than from gunshot wounds in various wars of recent years, makes the following significant statement: In the Crimea, the French lost 236 men from sickness to 64 from wounds in each thousand. The deathrate of the English was 179 from sickness and 47 from wounds. In Mexico the French lost, per 1,000, 140 from sickness and 49 from wounds. In the Russo-Turkish war, the Russians lost, per 1,000, 113 from sickness and 49 from wounds. The losses in the American Civil war during 2 years, June, 1861, to June, 1863, were 53.2 per 1,000, of which 8.6 were from wounds and 44.6 from sickness. In the Boer war, while the figures are not at hand in complete form, it is well known that sickness was vastly more fatal than Boer marksmanship, deadly as that was admitted to be. And yet any official status whatsoever is but grudgingly granted to the medical men in the army.

Successful Fight against Malaria in Egypt.—The *London Times* quotes Sir Alfred Jones in reference to his report of the work accomplished by Major Ross and others in Ismailia, Egypt. It appears that when Major Ross first began his work in Ismailia in September, 1902, there were 2,000 cases of malaria annually in a population of 9,000 people, of whom 2,000 were Europeans. The authorities at Ismailia carried out Major Ross's suggestions as to filling up marsh land close to the town, cleaning out small irrigating channels and stagnant waters. That involved an expense of £4,400, and at the same time they organized a drains brigade and petroleum brigade, as a result of whose work people can now sleep in any of the houses in the European quarter without mosquito nets. From 2,000 cases of malaria a year the number had been reduced to 200. According to Sir Alfred, tropical medicine was bringing us to think that after all this little country of ours had been for centuries teaching medicine applicable to our own country and domestic life without thinking of our great empire all over the world. The time had come when they must teach students a medicine applicable to the whole world. Major Ross holds that the success of the antimalarial campaign at Ismailia had taught two things—that it is possible to rid a large town entirely of mosquitos, and that it is equally possible to eradicate malaria.

Rio de Janeiro's Change in Quarantine Regulation.—An exchange states that Rio de Janeiro has abolished its old fashioned quarantine regulations, and vessels with cases of yellow fever on board will hereafter be simply disinfected and supervised. The change means a victory for that city's new Health Board, the head of which, after a great deal of hard work, succeeded in convincing the Brazilian Congress of the correctness of the Cuban theory regarding the propagation of yellow fever by mosquitos. Notwithstanding the success of the United States officials in completely ousting that disease from Havana, there was much opposition to the plan, but at last Congress voted the sum of \$1,250,000 for a war on mosquitos. Last October 1,200 men were engaged in destroying the larvae of those insects. The natives were at first inclined to laugh at this brigade, with its brooms, ladders, kettles, and cans of coal oil; but they became serious when they learned the result—only nine cases of yellow fever in the midsummer months of January and February, as against 275 cases in the same months last year. In the period from 1850 to 1896 the number of deaths from this disease in Rio, was 51,600. There have been times when as many as 2,000 patients were cared for in the isolation hospital, which is located near the cemetery and is known as the *antecamera da morte*. This hospital, which was an ideal focus for the propagation of the disease by infected mosquitos, and from which few patients used to emerge alive, is now closed.

OBITUARIES.

Israel T. Dana, at his home in Portland, Me., April 13, aged 77; a graduate of the Harvard Medical School in 1849. He was one of the founders of the Maine General Hospital and of the Maine Medical Association. He was formerly professor of materia medica at the Maine Medical School, Brunswick; he was one of the most prominent physicians of Portland and a member of a number of medical societies.

Joshua M. Carey, at his home in Mt. Vernon, N. Y., April 20, aged 70; a graduate of the Eclectic Medical Institute, Cincinnati, Ohio, in 1862. He served throughout the Civil war as an army surgeon of the Federal army, serving in 51 battles. He was formerly a member of the Pennsylvania State Legislature.

Andrew P. Cox, at his home in Coraopolis, Pa., April 21, aged 59; a graduate of Jefferson Medical College. He practised in Big Run, Pa., seventeen years before locating at Coraopolis. He was a wellknown physician and a member of the American Medical Association.

James S. Stevens, at his home in Kensington, Philadelphia, April 23, aged 71. He was a specialist in obstetrics and diseases of children, a Shakespearian scholar, and one of the oldest and best known physicians in the section of the city in which he lived.

Robert M. Read, of Boston, in Los Angeles, Cal., April 21, aged 56; a graduate of Harvard Medical School in 1876. Having engaged in active practice until the past few months when ill health compelled him to seek a different climate.

John I. Skelly, at his home in Pekin, Ill., from apoplexy, April 9, aged 57; a graduate of Detroit Medical College in 1869; member of the American Medical Association and a member of the hospital corps during the Civil war.

Wilbur F. Nutton, at his home in Newark, N. Y., April 18, aged 64; a graduate of the College of Physicians and Surgeons, N. Y., and a member of various local and State medical societies.

Josiah C. Donham, at his home in Hebron, Maine, April 7, aged 66; a graduate of the Medical School of Maine, at Brunswick, in 1867; one time representative in the State Legislature.

Sarah Fowler Stockwell, from cancer, at her home in South Bend, Ind., April 2, aged 62; a graduate of the University of Michigan in 1876; member of the American Medical Association.

John P. Manker, from paralysis of long standing, at his home in Chattanooga, April 9; a graduate of the Chattanooga Medical College in 1894 and an instructor in his alma mater.

John A. Pearsall, at his home in Saratoga, April 18, aged 53. He was a member of the New York Homeopathic Medical Society and of the American Institute of Homeopathy.

Cyrus Kindrick, at his home in Litchfield Corner, Maine, April 4, aged 78; a graduate of Jefferson Medical College in 1848 and a member of various medical organizations.

T. R. Rogers, at his home in Moundsville, W. Va., April 12, aged 70. He was a wellknown and respected physician in the vicinity in which he lived.

J. Howard Rabe, of Clyde, Ohio, after an operation for gallstone, in Philadelphia, April 2, aged 37; a graduate of Jefferson Medical College.

Thomas S. Clark, from paralysis, at his home in Vanceburg, Ky., April 4, aged 55; a graduate of the Medical College of Ohio, Cincinnati, in 1873.

James H. Crabbs, at his home in Fremont, Neb., April 9, aged 77; a graduate of the College of Physicians and Surgeons, Keokuk, Ia., in 1872.

Henry Lee, as the result of a fall of nine stories in an elevator shaft, in Chicago, April 24. He was a surgeon of some note in Chicago.

Cyrus R. Stuckslager, at his home in McKeesport, Pa., April 7, aged 75. He was a surgeon in the Federal army during the Civil war.

Weller Roos, at his home in Chenango, Forks, N. Y., March 31, aged 50; a graduate of Bellevue Hospital Medical College in 1883.

Thomas F. Jordan, at his home in Hickory Hill, Mo., April 7, aged 42; a graduate of the Missouri Medical College, St. Louis.

Romain C. Barless, at his home in Rose, N. Y., April 3, aged 70, a graduate of Jefferson Medical College, Philadelphia.

THE PUBLIC SERVICE

Changes in the Medical Corps of the U. S. Army for the week ended April 23, 1904:

PEASE, F. D., contract surgeon, is relieved from duty at Fort Assiniboine and will proceed to Missoula, Mont., for annulment of contract.

RUTHERFORD, First Lieutenant **HENRY H.**, assistant surgeon, is granted leave for one month on account of sickness.

PEASE, F. D., contract surgeon, is granted leave for twenty days, to take effect upon his arrival at Missoula.

STRAUSS, JULIUS, sergeant first class, is relieved from duty at Aparri, Cagayan, Luzon, and will be sent to San Francisco, Cal.

WHITE, J. SAMUEL, contract surgeon, is granted leave for one month, from about April 15.

So much of orders of March 29 as directs John G. J. Knust, sergeant first class, to join the first detachment of the hospital corps to be sent from the Army General Hospital, Washington Barracks, to the Philippine division, is revoked. Sergeant Knust, upon expiration of furlough authorized in letter from the War Department, April 14, will join the first detachment of the hospital corps to be sent from his station to the Philippine division.

GIBSON, Major **ROBERT J.**, surgeon, is relieved from duty at Iligan, Mindanao, and will report to the commanding officer, department of Luzon, for assignment to duty.

WALKER, Major PHILIP G., **WOLFE**, Captain **EDWIN P.**, and **SHOCKLEY**, First Lieutenant-Major **A. W.**, assistant surgeons, will proceed to Zamboanga, Mindanao, reporting to the commanding general, department of Mindanao, for assignment to duty.

WELLS, Major **GEORGE M.**, surgeon, and **HAMMOND**, **WILLIAM G.**, contract dental surgeon, will proceed to Iloilo, Panay, reporting to the commanding general, department of the Visayas, for assignment to duty.

GREGORY, **VERDO B.**, and **SABIN**, **WALLACE E.**, contract surgeons, will report to the commanding general, department of Luzon, for assignment to duty.

ARTAUD, **FRANK E.**, contract surgeon, is relieved from temporary duty at the Convalescent Hospital, Corregidor Island, and will report to the commanding general, department of Luzon, for assignment to duty.

REDDY, **JOSEPH W.**, contract surgeon, is granted leave for two months, with permission to visit the United States.

McMILLAN, **CLEMENS W.**, contract surgeon, will proceed at once to Fort Ethan Allen for temporary duty, and upon the completion of this duty will return to his proper station at Fort Myer.

THOMPSON, **HERBERT**, sergeant first class, now attached to company of instruction No. 2, hospital corps, Fort McDowell, is assigned to duty with that company.

WATERHOUSE, First Lieutenant **SAMUEL M.**, and **EDGAR, JR.**, First Lieutenant **BENJAMIN J.**, assistant surgeons, will report to Lieutenant-Colonel **George H. Torney**, deputy surgeon-general, president of the examining board at the United States Army General Hospital, Presidio, for examination for promotion. Upon the completion of his examination Lieutenant **Waterhouse** will comply with the requirements of orders of February 20.

McANDREW, First Lieutenant **PATRICK H.**, assistant surgeon, leave granted February 19 is extended fifteen days.

ALLEN, **IRA A.**, contract surgeon, leave granted January 30 is extended one month.

SCHREINER, Captain **EDWARD R.**, assistant surgeon, is granted leave for three months, to take effect when a medical officer is sent to relieve him.

JONES, First Lieutenant **PERCY L.**, assistant surgeon, will proceed to Washington Barracks for temporary duty, and upon the completion of this duty will return to his proper station at Fort Monroe.

COMEGYS, Lieutenant-Colonel **Edw. T.**, deputy surgeon-general, is relieved from duty at the United States General Hospital, Fort Bayard, to take effect at such time as will enable him to comply with this order, and will proceed to San Francisco, Cal., and report for transportation to the Philippine Islands on the transport to sail from that city about June 1.

Changes in the Medical Corps of the U. S. Navy for the week ended April 23, 1904:

STONE, E. P., surgeon, detached from the Mayflower and ordered to the Naval Academy—April 15.

PRYOR, J. C., passed assistant surgeon, ordered to the Naval Hospital, Newport, R. I.—April 15.

HOLCOMB, R. C., passed assistant surgeon, detached from the Naval Hospital, Newport, R. I., and ordered to the Mayflower—April 15.

STRITE, C. E., acting assistant surgeon, appointed acting assistant surgeon from April 13, 1904—April 15.

LOWNDES, C. H. T., surgeon, detached from the Naval Academy, and ordered to the Chesapeake—April 19.

DEVALIN, C. M., passed assistant surgeon, detached from the Rainbow, and ordered to the Albany—April 20.

TRAYNOR, J. P., assistant surgeon, detached from the Albany, and ordered to the Rainbow—April 20.

ARNOLD, W. F., surgeon, retired from active service April 19, 1904—April 21.

Changes in the Public Health and Marine-Hospital Service for the week ended April 21, 1904:

BROWN, B. W., passed assistant surgeon, granted leave of absence for two days from April 25—April 19, 1904.

BLUE, RUPERT, passed assistant surgeon, granted leave of absence for three days from April 19—April 18, 1904.

GREENE, J. B., passed assistant surgeon, relieved from duty at Havana, Cuba, and directed to report to medical officer in command at New York (Stapleton) for duty and assignment to quarters—April 20, 1904.

HOLT, J. M., passed assistant surgeon, to report to medical officer in command at San Francisco, Cal., for duty and assignment to quarters—April 20, 1904.

McLAUGHLIN, A. J., assistant surgeon, granted leave of absence for four days from April 20—April 20, 1904.

WARREN, B. S., assistant surgeon, granted extension of leave of absence for one day from April 17—April 20, 1904.

ASHFORD, F. A., assistant surgeon, leave of absence granted for ten days from March 28, 1904, amended so that said leave shall be for eleven days—April 19.

ALTREE, G. H., acting assistant surgeon, granted leave of absence for five days from April 19—April 19, 1904.

BAILEY, C. W., acting assistant surgeon, granted leave of absence for eleven days from April 22—April 20, 1904.

DUKE, B. F., acting assistant surgeon, granted leave of absence for six days from April 18—April 18, 1904.

MARSH, W. H., acting assistant surgeon, granted leave of absence for five days from April 26—April 20, 1904.

MONCURE, J. A., acting assistant surgeon, department letter of March 31, 1904, granting leave of absence for thirty days from April 10, 1904, amended so as to read thirty days from April 12, 1904—April 20, 1904.

ILTIS, G. W., pharmacist, granted leave of absence for twenty-five days from May 5—April 14, 1904.

SOCIETY REPORTS

GERMAN SURGICAL ASSOCIATION.

XXXIII Congress, Held at Berlin, April 6, 7, 8, and 9.

[Specially reported for *American Medicine* by Lawrence Hendee, A.B., M.D., Instructor in Anatomy, Cornell University, Ithaca; Z. S. Volontärarzt, Chirurgische Klinik, Königsberg, I/Pr., Member of the German Surgical Association, with due acknowledgment of Dr. Wohlgenuth, authorized reporter for the German Medical Press, and the members of the Association, who kindly furnished abstracts.]

The session was formally opened by Professor BRAUN (Göttingen). His opening address was devoted particularly to a review of the work done in medicine by the members who had died during the past year, *i. e.*, Geh. Rat. Feldmann, and Jürgens (Berlin), Schwalbe (Los Angeles), Tribitzki, (Krakau), Petri, Donold, Schatz, and Gussenbauer (Wien). He gave an especially warm tribute to Gussenbauer, reviewing carefully his work and effect on the scientific world in general. The work of the Library Committee was highly praised, and especially that of Professor Fischer (Berlin), a member of the committee, stating that it was due in great part to his personal work, covering a period of three and a half years, that the catalogue of the library had been finished and the library put in condition to be of use to the members. At the president's suggestion, a vote of thanks by the Association was extended to the Library Committee and Professor Fischer.

KÜMMELL (Hamburg) was elected second secretary of the Association. Geh. Rat. KÖRTE (Berlin), secretary, read the names of the new members—72 in number.

Suturing the Bloodvessels in Arteriovenous Aneurysm in the Popliteal Space.—KÖRTE (Berlin). The case was that of a boy 13 years old, who was stabbed with a pocket-knife in the right popliteal space. The wound at the time was sutured. Eight days afterward patient came under his observation. There was a small freshly healed wound, in which pulsation was plainly felt; auscultation gave a buzzing sound, synchronous with the radial pulse, but no aneurysmal tumor was visible. At operation, eight months later, the vessels were freed and cleaned, and the vein and artery were found to be joined for about 6 mm. They were isolated and separated along the line of junction. The opening in the walls of both artery and vein was closed by a very fine linen suture and the wound dressed with compression. Five months later the wound was well healed, showing a firm scar, and the pulse in the popliteal and tibial arteries plainly discernible with no venous pulsation.

Clinical and Experimental Contributions to Arteriovenous Aneurysm.—FRANZ (Berlin) first reported a case similar to Körte's, occurring in Von Bergmann's clinic. In this case he considered it necessary to ligate the vessels as there was considerable rise in temperature of the lower extremities, while as a rule in such cases there is usually a fall of temperature. He then presented the results of experiments in animals, which he had been conducting for some time. In his experiments he joined by opening and suturing together the artery and vein. In each case immediate venous pulsation was noticed. The arterial stream in the vein in a short time flowed toward both the distal and proximal portions of the vein. Because of the course of the arterial blood in the vein, he considered simple ligation of the vein on both sides of the fistula sufficient.

Demonstration of a Preparation of Arteriovenous Aneurysm from an Unusual Cause.—REISE (Britz). The chief point of interest was the cause of the aneurysm; it being due to an injury to the bloodvessels by a splinter of bone separated and unobserved, while chiseling during a bone operation.

Interosseous Bloodvessels (Arterial) and their Relation to the Etiology of Bone Disease.—LEXER (Berlin). This was one of the most interesting papers presented during the morning session. Lexer first referred to his former report, made in the congress of the preceding year, principally upon investigations of the interosseous arterial vessels of the bones of newborn. During the past year the investigations were extended, including those of children, young adults and advanced age. The investigations were principally anatomic in character. He used for injection mercury suspended in oil of turpentine, the injection being carried to a point where the injected vessels were plainly visible beneath the raised peritoneum. Röntgen ray pictures then were taken, the injected vessels standing out distinctly. He found the picture given by the interosseous vessels to vary in relation to the age of the bone, particularly in the number and anastomosing of the metaphyseal vessels. In relation to the age of the bone there was a decrease in number as well as the anastomosis with the diaphyseal arteries. The same condition was found to be present in short bones with the exception that they did not have the special locations or districts of bloodvessels. He held that the free anastomosis of the metaphyseal interosseous arteries played an important role in the young in the location of infection through the blood channel; especially in osteomyelitis, tuberculosis, metastatic tumors and parasitic infection. He also included through its mechanical influence the lesions caused by lodgment of emboli. He considered that this theory was upheld clinically as the above diseases were comparatively rare in older bones. In the evening session he gave a lantern exhibit of his preparations, showing

ing about 40 examples. The exhibit was an interesting as well as an instructive one. (The entire collection of negatives will be sent to the St. Louis Exhibition, to be placed in the collection of exhibits from Von Bergmann's clinic.)

The Arrangement of the Vertebral Arteries in Scoliosis.—HOFFMAN (Graz) exhibited diagrams showing the relation of the arteries of the normal vertebral column as compared to those in scoliosis. In the normal vertebrae he claimed the arteries take a regular course passing from anterior to posterior in a direction regularly upward or downward. In scoliosis he found them passing straight backward, neither going upward nor downward, and that they were frequently bent and irregular in their course.

Discussion.—LEXER (Berlin) held that there was no regular course for the arteries in either the normal or in scoliosis. HELFERICH (Kiel), referring to Lexer's article, first agreed with him as regards the relation of the interosseous arteries and the etiology of bone disease. Continuing further he disagreed with Hoffman as regards the regularity of arrangement of the arteries in the normal as well as in scoliosis. ASHOFF (Munich) asked if all bone metastasis could be accounted for by Lexer's theory. He mentioned Recklinghausen's theory as regards the etiologic factor of injury.

Experimental Investigation in Regard to the Effect of Sodium Fluorid upon Bone, Especially the Maxillary Bones.—STUBENRAUCH (Munich) found that by adding sodium fluorid to the diet of young dogs there resulted a typical caries of the teeth, with great porosity of the bones of the extremities. However, there was no interference in the growth of the bones.

Demonstration of Preparations from a Case of Multiple Bone Sarcoma with Osteitis Deformans.—REHN (Frankfurt, a/M). The case reported was that of a girl 23 years old. Patient had pain for some time in right hip. Ten months after commencement of observation there developed a tumor. Operation and removal of tumor. Microscopically the tumor gave the appearance of a myeloid sarcoma. Two months later there appeared a tumor on the left pelvic bone, and still later tumors on the femur, several ribs, and lower extremity. The bones had a consistency like that found in osteomalacia. He was in doubt as to whether the multiple tumors were true neoplasms or not. In none did the microscopic examination give a true sarcomatous picture. He thought that they might possibly also be new formations, due to inflammatory reaction.

The End-results of Plastic Operations on Tendons, with Demonstration of Patients.—HOFFA (Berlin), in introduction, spoke of the importance plastic operations on tendons had reached, and referred to the work his assistant—Koch—had done in regard to such operations when there were defective or paralyzed muscles. Fourteen patients were presented upon whom he had operated. The operations were along the line of tenorrhaphy and tendon transplantation. The tendons he had operated on included tendon achilles, quadriceps extensor, triceps, and those attached to the external and internal condyles. He recommended the combining of the methods of Nicoladoni and Lange so that the best results could be obtained.

Implanted Carcinoma.—PETERSON (Heidelberg) stated that all cases in which the carcinoma cells had left the original tumor and located in some other situation, could be classed as implanted or transplanted carcinoma. This implantation might come by continuity, blood stream, lymph stream or by direct transplantation from one body to another and also by continued contact with a surface. The three surfaces especially mentioned were serous, epithelial and wound. He held that those involving wound surfaces to be of the most interest to the surgeon. In this connection he mentioned the possibility of such infection—in Schuchardts' paravaginal incision for the removal of a carcinoma of the uterus, but further stated that this instance could not be held as a perfect example as one could not be certain of the existence or not of a previous infection through lymph channels.

Late Recedive of Carcinoma.—JORDAN (Heidelberg) held that recedive of carcinoma was a problem including both the prognosis (dauer Heilung) and the etiologic cause or condition, the form or type of the carcinoma being often the key to the problem. If in the primary operation carcinoma cells were left behind, it then depended upon their malignancy to how soon new tumor formation or building began. He quoted two cases. *First case* was a recedive occurring 19 years after primary operation. The primary tumor was an epithelioma of the tongue (operation 1885). Early in 1904 a recedive was noticed on the old scar. In March, 1904, he performed operation with extirpation of the tumor. The deeper and more distant cervical lymph-nodes were not involved. *Second case* was that of mammary carcinoma with several recedives occurring during 15 years. In 1889 he amputated a mammary carcinoma, the first recedive occurring in 1892, the second recedive in 1896, the third in 1899, the fourth in 1901 and the fifth in 1903. The lymph-nodes in the subclavicular and supraclavicular glands were involved and were extirpated. Each recedive except the last was local in character. Since the last recedive there have been as yet no signs of recurrence. Jordan claims that if the statistics of carcinoma should be revised and more careful observations made, many cases of so-called permanent cure would be placed in the list of late recurrence.

The Physiologic and Physical Bearing on Intrathoracic Operations of His Pneumatic or Vacuum Operation—

room.—SAUERBRUCH (Breslau). His vacuum room consists of an air-tight operating-box large enough for the table, operator and assistants. The patient's head is outside the operating box, a rubber curtain fitting around the neck preventing the ingress of air. By means of an air-pump the air in the room is reduced to a vacuum equal to 10 mm. of mercury (giving the same air-pressure as an elevation of 300 meters). By this means the internal pressure of the lung is greater than the external so that on opening the pleural cavity there was no pneumothorax or collapse of the lung. As yet experiments have been conducted with but one exception, on dogs. What the result in all cases on man as far as affecting the heart action is concerned is not known. The experiments are still in the physiologic stage and have been successful. Demonstrations on dogs were given daily and were quite interesting.

Surgical Possibilities of the Sauerbruch Operation-room.—MIKULICZ-RADECKI (Breslau) dwelt on the possibilities and increased field of thoracic operations by this new method. He especially mentioned the removal of the chief difficulties in transpleural and transdiaphragmatic operations; also the increased possibilities in operations on the esophagus. Considerable amusement was caused by his suggestions of its application to heart surgery, even to operations on the mitral valve. He was quite pleased with the results of the experiments on animals. In closing, he spoke of a case in which a man was operated on by the new method but died of heart collapse which he did not consider due to the method.

A Modification of the Sauerbruch Method to Prevent the Complication of Pneumothorax.—BRAUER (Heidelberg) stated that his modification was based on the increase of the internal lung-pressure above normal rather than the decrease of the external. The increase of this pressure was obtained by the use of special apparatus in combination with the anesthetic whereby internal pressure could be increased and regulated. There were two methods of its administration: 1. Through a tracheotomy. This was chiefly for animal experiments, but could be used in man when such a procedure was justified. 2. By a Waldenburg ether mask and an air-pressure apparatus. Brauer had perfected an apparatus consisting of a box fastened around the patient's head, in which by a Roth-Dräger chloroform apparatus the anesthetic could be easily administered. Holes protected by rubber curtains in the box were for the assistant through which his arm went in administration of the narcosis. Brauer claimed his apparatus was as effective as that of Sauerbruch's and had the added advantage of simplicity and inexpensiveness.

Intrathoracic Operations.—PETERSON (Heidelberg) demonstrated an apparatus similar to Brauer's, for which he claimed superiority over both Brauer's and Sauerbruch's. He also raised the point of the beneficial effect of lung gymnastics. He reported one case of a man operated on for a tumor of the dorsal vertebra involving the pleural cavity, in which his pressure apparatus was used with good results. Unfortunately on the first dressing, three days after operation, the apparatus was not used—the lung collapsed, and death followed.

Discussion.—An animated discussion between SAUERBRUCH, BRAUER, and PETERSON followed; no new points, however, were brought out. MÜLLER (Rostoch) suggested that they wait and report again next year after further investigation.

Report of Cases on Which Cardiomyolysis Had Been Made.—BECK (Karlsruhe). Three cases were reported. First case, that of a boy suffering with ascites and engorgement of both liver and kidneys. The heart action was very irregular and weak. At operation resection of the fourth, fifth, and sixth ribs was done and cardiomyolysis performed. On the heart and pericardium were found fungoid masses, with numerous firm adhesions. During the first three days after operation the heart action was very bad. On the fourth day the boy began to improve, and was soon completely recovered, with disappearance of all symptoms that were present before operation. At present he is able to do active athletic work. In the two other cases, firm adhesions were encountered, and after the operation both patients recovered, and are at present in excellent condition. Beck considered the operation to open a new field in surgery, and that it was particularly applicable after pleuritis or pericarditis when the adhesions formed caused severe interference to the heart's action. In his technic he made a rib section, then opened the pericardium longitudinally.

Upon the Question of Röntgen Ray Treatment of Carcinoma.—PERTHES (Leipzig) reported 29 cases of carcinoma treated by the röntgen ray. Thirteen cases were of the epithelioma type, involving the skin. Of these, 12 are healed with a good scar. The one still remaining was a very large, deep ulcer. Three of the cases have been under observation 10 months and show no signs of recedive; three others must be further treated because of the lymph-node involvement. In the cases of carcinoma involving the mouth cavity or tongue, he had no definite results. In eight cases of inoperable carcinoma of the breast, he has had a decrease in size of the tumor with scar formation, but as yet is not able to report complete healing in these cases. In his technic he uses for the skin carcinomas a medium strength ray as measured by the Holzknecht chromodimeter, the length of treatment being about 15 minutes daily, obtaining his results in from 24 days to 70 days. In three cases of carcinoma of the lip he used the full strength ray, with results in from 50 days to 60 days. The cases of carcinoma of the lip have been under observation seven months

without the appearance of recedive. He considers the röntgen ray treatment of great advantage in epithelioma of the nose or eyelid, as it leaves them in condition for better function and also better results from a cosmetic standpoint. In epithelioma of the lip in patients of advanced age he advises the use of the röntgen ray in combination with the knife. In all cases he advises the use of the knife for the lymph-nodes. He found the intensity of the rays by measurement to be reduced at least a half by the passage through the skin. He found the decrease in size of the tumors began before the appearance of the inflammatory reaction. Histologically, he found degeneration of the carcinoma cells. By experiments on the eggs of *Ascaris megalocephala* and hens, he found cell growth prevented or halted by the röntgen ray.

Röntgen Ray Therapy.—LASSAR (Berlin) presented a large number of patients who had been treated by the röntgen ray. The list included ulcus rodens, actinomycosis, eczema, epitheliomas. In each case there was excellent scar formation as well as cosmetic results.

Lantern-slide Demonstrations of Anatomic Investigation on the Motor Centers of the Brain.—KRAUSE (Berlin). His investigations were made on the brains of individuals during the course of operation for epilepsy.

Slides Showing Different Types of Cell Collections and Forms in Carcinoma of Uterus, Vulva, and Rectum With a Comparison of the Malignancy of the Different Forms.—PETERSON (Heidelberg) found that carcinoma simplex gave the highest percentage of positive recovery—carcinoma papilliform and solidum standing next—while carcinoma adenosa, gelatinosa gives nil percent (0%) recovery.

Röntgen Ray Pictures of Paget's Disease of the Bones.—HOFFA (Berlin) presented pictures of bones of the lower extremity in three cases that came under his observation.

Physiology and Pathology of Prognathia.—SCHROEDER (Greifswald) presented demonstrations of the form of the supermaxilla and the position of the teeth in prognathia; also his apparatus for the treatment of the condition.

Demonstration of Various Röntgen Ray Pictures.—IMMELMAN (Berlin). His demonstration was confined to pictures of the hip-joint before and after the reduction for congenital dislocation. He presented pictures of 13 cases, the age of the patients varying from 3 years to 11½ years.

Etiology of Foreign Bodies in the Knee-joint.—HOLLANDER (Berlin) first presented pictures illustrating the various forms of capsular disease, then röntgen ray photographs, showing foreign bodies in the joint.

A Case of Phocomelia.—HIRSCH (Berlin) presented röntgen ray pictures of the bones in the deformed upper and lower extremities.

TREPLIN (Hamburg) presented röntgen ray pictures of a case of diverticulum of the esophagus.

BOCKENHEIMER (Berlin) demonstrated his apparatus for lighting up the mouth and throat for examination.

Five New Operations on the Liver and Gall-system.—KEHR (Halberstadt). The first case was that of ligaturing the hepatic artery for aneurysm. His diagnosis before operation was gallstone in gallbladder, which on opening the patient turned out to be an aneurysm of the hepatic artery. He amputated the gallbladder, as he feared that necrosis of the sack would follow the ligation of the artery. Result, good recovery. He considered that aneurysm of the hepatic artery was a condition that should always be borne in mind, though not frequent, it occasionally was encountered. Second Case.—Resection of the ductus choledochus and hepaticus with hepaticoduodenostomy. The patient had a tumor of the two ducts, necessitating their removal. Kehr claimed this as the first case of extirpation of the gall-passages. (Recovery?) Third Case.—Gallstone operation; found a defect in the duodenum, the duodenum being practically closed. He performed gastroenterostomy. Fourth Case.—Found it necessary to do a hepatocholeogastroenterostomy, exitus of patient within a week. Fifth Case.—Kehr found an implantation of the fistel of a pancreatic retention cyst into the gallbladder. He performed a cystogastrostomy. The stomach appeared to bear the pancreatic secretions well. Presented the patient.

Experimental Investigation into the Condition of the Stump after Cholecystectomy.—HABERER and CLAIRMONT (Wien), read by Haberer. The experimental work of Nasse, reported in twenty-third Congress, of Oddi and of Voegt, was first reviewed. As Nasse claimed that new cystic formation did not occur, and Oddi and Voegt claimed that it did, Haberer took pains to state the difference in technic between them; the principal point being that Nasse removed the gallbladder and duct completely, while Oddi and Voegt left part or the entire cystic duct. He compared the statement of Riedel, that a large stump or duct remaining after cholecystectomy was dangerous, with that of Kehr's (1901), who had found new bladder formation when a part of the duct was allowed to remain. The experimental research of Haberer and Clairmont covered 13 cases, the animals being dogs and cats. In 10 cases the gallbladder was removed but the entire duct allowed to remain. In two cases both the gallbladder and duct up to the common bile duct were removed. In one case the gallbladder and part of the duct were removed, a piece .5 cm. long of the duct being allowed to remain. The animals were killed from one to seven months after the operation, and in most cases the bile passages injected by Teichman's method. The results of the experiments were

as follows: In each case (10) of pure cholecystectomy, it was found that in a short time the distal end of the remaining cystic duct showed new bladder formation or dilation, while the proximal portion of the duct showed no dilation or enlargement. The picture was that of a small, and in some cases large bladder-like formation, with a distinct outlet and lumen. The same formation was seen in the case in which a piece of the cystic duct .5 cm. long was allowed to remain. In the two cases in which the entire duct with bladder had been removed, no new formation or dilation was to be seen. In conjunction with his animal experiments, he reported two other cases in man, which by good fortune came into the anatomic rooms, each patient some time previous having had a cholecystectomy performed. In both of these cases new bladder formation was observed, the same as in his animal experiments. In each case only that which had a distinct outlet and lumen was considered as new bladder formation. His explanation for the new formation is that after the operation, the bile, as before, flows into the cystic duct and tends to collect and remain at the distal end, thereby causing traction and dilation. This condition tends to increase automatically, as with increased dilation comes an increased amount of bile in storage, with increased weight, and therefore increased dilation or sac formation. When the cystic duct is completely removed there is no place or chance for the bile to collect and form a reservoir. In closing, he considered it proper, from the results of the experiments, for the surgeon to leave as much as possible of the cystic duct, in order to provide for new bladder formation.

The Operative Removal of a Gallstone Situated in the Duodenal Portion of the Common Bile Duct.—KRASKE (Freiburg) spoke of the increased difficulties of the operative removal of a stone occupying such a position. He preferred first, if possible, by manipulation to render the stone movable and then push it toward the upper portion of the duct, away from the neighborhood of the duodenum and pancreatic duct, before opening the common duct. The possible injury to the mucosa of the lumen of the common bile duct, and also the pancreas, must be borne in mind. If the stone is located in the diverticulum of Vater, he opens the duodenum in order to remove it. He reported two cases. In the first case the pancreatic duct was injured (?) in the manipulation of the stone. The patient died five weeks after operation, from inanition. Second case.—Opened the common bile duct near the duodenum. The sutures held for three days; the fourth day they gave away. Patient died.

Discussion.—ENDERLEIN (Marburg) had performed hepatocholeogastrostomy on animals, the results of which were not such in his opinion to warrant its performance in man. HIRSCHBERG (Frankfurt, a/M) thought in the case reported by Kehr, that there was a possibility that the anastomosis had not held permanently and that the bile had sought a natural way by itself. RIEDEL (Jena) considered it quite important in operations for a gallstone in such a position to have an incision by which the liver could be raised up and the entire course of the bile ducts seen. For this he recommended his incision which he commenced at the ensiform appendix and carried down in the middle line considerably below the umbilicus. PETERSON (Heidelberg) reported the results of such operations in the Heidelberg clinic. HEIDENHAIN (Worms) demonstrated his new instrument for the removal of the stone. PAYR (Graz) mentioned the occurrence of arteriohepatic aneurysm which might give the same clinical picture. He had had one such case. KAUSCH (Breslau) stated with the stone in the duct near the duodenum, the duct and not the duodenum was opened whenever possible. He claimed that if the suture in the common bile duct did not hold, the most that occurred was a biliary fistula, while if the suture in the duodenum failed to hold it caused the death of the patient. He considered Riedel's incision as improper. Personally he recommended an incision following the course of the lateral abdominal nerves. KEHR (Halberstadt) considered the opening through the duodenum the best. He stated he had had 20 such cases, but with two deaths, one of which had a defect in the duodenum so that he found it necessary to tamponade the wound into the duodenum.

Report of a Case of Papillary Epithelioma of the Gallbladder.—PELS-LENSDEN (Berlin). In this case no gallstone was found. The microscopic examination showed a similarity in structure and cell formation with those found in the bladder. Presented the patient.

Surgical Treatment of Hepatoptosis by Laparotomy and Hepatopexy.—MAYER AND DEPAGE (Brussels) reported a case of a 34-year old woman with the following operative technic: Patient was placed in Trendelenburg's position (with the hips high), by means of which the liver occupied a much higher position. An incision 15 cm. long and parallel to the lower costal border was made. The upper lip of the parietal peritoneum was then turned around under the lower border of the liver and there fixed by catgut sutures. The wound was closed by continuous sutures. The case has now been under observation for four months, and up to the present the operation appears to be successful. Depage, in 1893, had adopted the method of shortening and fixation of the ligamentum teres. Four cases in which there were markedly pendulous abdomens have been operated on by this method. These cases have been under observation for from three to eleven years and show as yet no recurrence.

Traumatic Rupture of the Liver.—GRASER (Erlangen) reported a case, the patient having had very severe pain in the stomach for eight weeks; there then developed a very large left-sided tumor, reaching to the anterior spine of ilium. Tumor gave fluctuation. Diagnosis, soft sarcoma. Operation. Exploratory puncture gave pus. On opening he found a large cavity filled with pus, in which were several detached masses that, on examination, proved to be detached and necrotic pieces of liver substance. In the previous history it was found that the patient five years before had fallen a distance of 15 feet, striking on his side. Diagnosis after operation was that of an old liver rupture with separation of several portions of liver substance. He considered the source of infection to be through the blood channels. He based this upon the results of a case in which he had examined the portal blood six times, and each time had found streptococci, from which he concluded that the blood coming from the intestines to the liver always carried a large number of bacteria.

Gunshot Wound of the Abdomen Involving the Stomach, Liver, Spleen and Kidney.—RIESE (Britz). The principal point of interest was the extent of the injury and recovery of the patient. In injuries to the liver he recommended suturing and drainage.

The Surgery of the Diaphragm.—NEUGEBAUER (Mährisch Ostrau) after a few preliminary remarks demonstrated several patients in which he had operated on the diaphragm with good results.

The Connection Between Disease of the Bile Ducts and Inflammation of the Pancreas.—KÖRTE (Berlin) considered disease of the bile passages to have an important etiologic bearing in pancreatic disease. He spoke of two paths for the extension of the disease. (a) Through contact in the intrapancreatic portions of the duct. This also involving the lymph-nodes. (b) From the mouth of the common duct in the diverticulum. This he again subdivided into: 1. Both openings being on the floor of the diverticulum. 2. One duct opening on the lateral wall of the diverticulum. 3. Both openings being situated on the apex of the papilla. In conjunction he mentioned the following cases: Two cases of abscess in the head of the pancreas. Two cases of peripancreatic abscess. One case of acute fat necrosis and pancreatitis. Two cases of necrotic pancreatitis associated with fat necrosis. The etiology of the above cases was as follows: One case of pancreatic stone. Four cases of gallstone in common duct. One case with several small stones in the common duct. One case of acute cholecystitis with liver abscess. He gave the following symptoms for the pancreatitis: 1. Epigastric pain. 2. Vomiting, peritonitis involving particularly the upper part of the abdomen. 3. Collapse. 4. Occasionally tumor felt. 5. Fever. This last is not always constant as one case was without fever. Of the seven patients four died, three recovered. In five of the cases the gallstone alone was removed with drainage. One case of gallstone and liver abscess—abscess opened—drainage (recovery). One case of pancreas freed—necrotic fat removed and drainage.

Report of Experimental Investigation of Peritonitis from Infection from Biliary Passages.—ERHARDT (Königsberg) had conducted his examinations in animals. He made an artificial biliary fistula. He found *Bacterium coli communis* to be the most frequent cause of the peritoneal infection, but that in virulence it was exactly opposite to its customary virulence when coming from the stomach or intestine. In fact, if the infection from the bile is due to the agency of *B. coli communis*, the prognosis is distinctly more favorable. In 17 animals the infection was due to *B. coli communis*, and of the 17, 12 recovered.

Injury to the Pituitary Body.—MADELUNG (Strasbourg) reported a case of a girl 9 years old, who three years previous was shot in the head, the track of the bullet leading to the pituitary body. The body-weight, since the injury, had increased 42 kilograms, the increased being due in the most part to increase of fat.

Discussion.—STOLPER (Göttingen) mentioned a somewhat similar case in which there had also been great increase in the body-weight. BENDER (Berlin) also mentioned a case in which he had noticed a great increase in the size of the bone structures, after injury to the pituitary body. KRONLEIN (Zurich), VON EISELSBERG (Vienna) mention experiments they had performed on cats, removing the entire pituitary body. All the animals died. They now intended to continue their experiments, causing only an injury to the pituitary body, to note the results.

Psychic Disturbance from an Abscess in the Temporal Lobe.—BORCHARD (Posen) held that the resulting psychic symptoms occurring in disease as compared to injuries involving the frontal or temporal lobes were exceedingly puzzling to account for, especially why after operation or injury to these portions, psychic symptoms were exceedingly rare, while in abscesses or tumors involving the same regions psychic disturbances, such as depravation of character, sexual cynicism, etc., were often encountered. He advanced the theory that possibly they may be due more to the traction of the tumor or disturbances of circulation in abscess or inflammation than to the actual injury itself. He reported a case of a girl 8 years old, who was injured in the left temporal region. Trephining was performed and brain substance as deep as the lateral ventricle was removed. At this time no psychic disturbances appeared; nine months later there developed an abscess in the temporal

lobe, and then appeared the special psychic symptoms affecting the character, and also sexual symptoms. After opening and drainage of the abscess—which was about the size of a walnut, the psychic symptoms disappeared immediately. Occasionally since then the scar of the wound became hard and firm when psychic disturbance affecting the character appears, but disappears as soon as the scar returns to normal. The case now has been under observation about six years.

Discussion.—FRIEDRICH (Leipzig) mentioned a case that came under his observation, which had had an extensive injury to the temporal lobe, with psychic symptoms following.

A Case of Thrombosis of the Cavernous Sinus, with Recovery.—HILDEBRAND (Basel) reported a case, giving the history in detail, the principal points of which were as follows: The patient (man) had the right nostril cauterized for chronic nasal catarrh. Two days later fever appeared, with angina. Temperature went down, but patient had headache, with some swelling of the right nostril. Shortly after, the patient became restless, slept poorly. Temperature, 39° C.; pulse, 58; nausea, headache; pupils contracted, with poor reflex. The next day ptosis, right side; paralysis of the adductors. By evening pulse 52, temperature 40° C., some protrusion of right eyeball. On following morning marked protrusion of eyeball and immovable, complete ptosis of over-lid, eyeball somewhat edematous, temporal and superior maxillary regions somewhat swollen, right pupil larger than left without reaction, left pupil very small. Aside from the eschar and some catarrh symptoms, nothing to be observed especially in nostril. Temperature, 40° C.; pulse, 60; veins on the background of the eye congested. Tavel's antistreptococcus serum injected. Temperature shortly after greatly decreased. The eye appeared improved. Five days later again high fever, but with frequent pulse; erysipelas serum exanthem in injection points. Two days later temperature normal. All the various symptoms gradually disappeared, patient fully recovered. Diagnosis was certain from the various symptoms. He called attention to the early paralysis of the adductors and its late disappearance, accounting for it by its closer anatomic relation to the sinus while the ophthalmic branch from the fifth lies more free. He considered that the infection probably came by way of the ethmoidal veins.

Experimental Investigation of the Effect of Thyroidectomy on the Sexual Functions.—LANZ (Amsterdam) credited Wharton with first calling attention to the connection between the thyroid gland and the sexual function. Following he mentioned the works of Schiff, Trachewsky, Halsted, and Von Eiselsberg on this subject. He reported the results of his own investigations. The following is the series of his animal cases: First Case.—Hen; thyroidectomy; decrease in weight of egg to 5 gm., while by a control the egg weighed 50 gm. to 60 gm. Second Case.—Cat; thyroidectomy. Tetany followed shortly after; death; negative. Third Case.—Dog (male); thyroidectomy; before operation actively motile spermatozoa were found; after operation spermatozoa disappeared and did not reappear later. Fourth Case.—Partial thyroidectomy; a sixth of the gland allowed to remain; no effect in sexual functions. Fifth Case.—(Female). Iodin injection in thyroid. Within a year the gland was markedly atrophied. Animal became sterile. Sixth Case.—Gland in a pregnant animal in the greater part removed. Caused remarkable change in both mother and young. Hofmeister and Von Eiselsberg were credited with the work of establishing the relation between thyroidectomy and chronic cachexia of the young. Results of experiments with serum therapy after thyroidectomy as regards their ability to propagate. First Case.—Male and female pups under six months; thyroidectomy; cretinism and complete and permanent loss of ability to propagate. Second Case.—Three months old goat (female); thyroidectomy; very little reaction; goat developed slowly; never reached full size; fat and in fair condition. Able with constant serum therapy to propagate, although propagating function greatly decreased. Young occasionally showed cretinism. All the young failed to develop to full size, but mentally were normal. In thyroidectomy of pregnant animals he found that shortly after delivery the milk disappeared and the breasts atrophied completely. In two cases of complete thyroidectomy in humans that came under his observation, the man lost his potency immediately, while in the woman the chief symptom was the disappearance of menstruation.

Report and Demonstration of Several Cases of Plastic Operations.—KAUSCH (Breslau). The cases demonstrated were those of contusion wounds of the hands with great laceration of the tendons, one case of scrotum torn away, and cases of laceration of the thigh, and one of the nose.

A Case of Operative Reposition of Old Irreducible Luxation of the Inferior Maxillary Articulation.—SAMTER (Königsberg). Patient demonstrated.

Extirpation of the Pharynx and the Upper Cervical Portion of the Esophagus.—GLÜCK (Berlin) exhibited a large number of charts illustrating the various steps of his operation. Also how the patient was fed through his artificial pharynx and esophagus. He reported that in 11 cases operated on by him, he had had 10 recoveries. He tasted that the patients were able to swallow and also speak fairly loud after the operation and insertion of artificial pharynx and esophagus.

The Catgut Suture for Patellar Fracture.—RIEDEL (Jena) demonstrated patient showing excellent results from the use of catgut for suturing a patellar fracture.

Treatment of Luxation of the Patella.—GRASER (Erlangen) reported several cases of repeated luxation of the patella outward—onto the condyle—the patella being also somewhat obliquely rotated. These cases were complicated by genu valgum. He obtained very good results—reduction of the luxation, then performing osteotomy on the condyle, turning it inward. He demonstrated several patients.

Total Extirpation of the Scapula.—BOCKENHEIMER (Berlin) demonstrated two patients (boys) on whom total extirpation of the scapula was performed. One for chronic and the other for acute osteomyelitis. Extirpation was performed by the subperiosteal method. No muscles or nerves were injured. In both cases the scapula is completely regenerated, though not anatomically perfect. In both cases there is excellent function of the arm. One of the patients is an acrobat, the operation having in no way interfered.

HAHN (Nürnberg) demonstrated the preparation and patient having a large tumor of the scapula, with extirpation of scapula. The second demonstration was a case of total extirpation of the scapula for osteomyelitis.

BENNECKE (Berlin) demonstrated the patient and röntgen ray pictures of progressive luxation of the wrist-joint.

IMMELMANN (Berlin) demonstrated the patient and showed röntgen ray pictures of traumatic edema of the dorsal side of the hand.

[To be continued.]

Consumption of Alcohol in the United States.—The following figures representing gallons consumed per capita extend a comparison over a period of above 30 years:

	Malt Liquors	Distilled Spirits	Wines
1903.....	18.01	1.46	0.48
1902.....	17.49	1.36	0.63
1901.....	16.20	1.33	0.37
1900.....	16.01	1.27	0.40
Five-year average:			
1895-99.....	15.34	1.09	0.34
1890-94.....	15.13	1.44	0.43
1871-75.....	6.73	1.59	0.44

The consumption of malt liquors has increased steadily throughout this period and is especially marked in the past few years. The per capita absorption of beer is nearly three times larger than it was 30 years ago, and it is to be particularly noted that the consumption of hard liquors and wines meantime suffers no material decrease relative to population. The additional 11 gallons of beer taken on by the average person since 1870 have not served materially to reduce the load of whisky and the like formerly carried, and have been accompanied by some little increase in the load of wine. The greatly enlarged consumption of beer, in other words, supplements and does not displace the old consumption of distilled spirits and wines. —[Springfield Republican.]

Association of Assistant Physicians of the Ohio State Hospitals.—The third meeting was held April 6 and 7, at Gallipolis, Ohio. The president's annual address, "The Reasons for the Existence of the Association, and Its Policy," by G. T. Harding, Jr., of Columbus, protested strongly against a niggardly economy to the detriment of the best medical work in these institutions. J. O'Brien discussed two cases of presenile delusional insanity observed at the Massillon State Hospital and at the McLean Hospital. Ralph W. Holmes, of Gallipolis, presented the specimens from a case of epilepsy following scarlet fever, in which the accessory sinuses on the left side were found at autopsy enormously enlarged and the left half of the cerebrum destroyed in large part. Here the aphasia following the disease gradually subsided and speech was regained while the patient became left-handed. E. B. Morrison, of Gallipolis, exhibited an epileptic patient with facial hemiatrophy. Wm. H. Pritchard, of Gallipolis, gave the clinical history and presented the pathologic specimens from a case of paradoxical embolism due to a persistent foramen ovale. Walter H. Buhlig, of Gallipolis, presented an epileptic with astasia-abasia. Arthur G. Helmick, of Gallipolis, read the clinical history and showed the specimens from an epileptic who died from measles and laryngeal diphtheria. F. D. Ferneau, of Toledo, read a paper with the subject, "Tuberculosis in the Insane." Inasmuch as this is a question now being debated by the medical profession and the legislative bodies of Ohio, and as it concerns directly the treatment of the tuberculous patients in the various State hospitals, it was freely and intelligently discussed by the members of the Association. A. P. Ohlmacher, of Gallipolis, presented and discussed the pathologic specimens in "A Case of Acute Sudden Death of Status Lymphaticus in an Epileptic." Officers: President, Wm. H. Pritchard, Gallipolis; vice-president, Paul W. Tappan, Dayton; secretary, Walter H. Buhlig, Gallipolis; treasurer, F. D. Ferneau, Toledo. As a result of the discussion of Dr. Gaver's paper on needed reforms in Ohio's lunacy laws, the legislative committee was charged with making a study of these laws in order to bring up for consideration at a future meeting such changes as seemed needed. Ralph W. Holmes, Gallipolis, James F. Kelley, Cleveland, and Mylo Wilson, Athens, were appointed by the president to represent the interests of the Association at the meeting of the Ohio State Medical Association, to be held at Cleveland.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

TYPHOID PERFORATION.¹

BY

WILLIAM STEWART FULTON, M.D.,
of Wheeling, W. Va.

On January 1, I was called to see A. H., a young boy of 14, who seemed to be suffering from an attack of grip. He complained of headache, backache, and muscular soreness. An examination showed his temperature was 102°; pulse, 100; no swelling or tenderness of abdomen; tongue coated. His mother said he had not been feeling well for two or three weeks; bowels had been constipated for some time; appetite not good, and that he had been restless at night.

Calomel was prescribed in broken doses, to be followed by a saline purge. A liquid diet was ordered and the patient was to be kept in bed until my next visit, which was on the day following, about noon.

On this second visit I found his temperature normal; his pulse 80, and of good quality. His bowels had moved well and he was hungry and wanted to get up; his tongue, however, was still coated. I advised his mother to keep him in bed until the following morning, when, if he still felt better, she might let him get up and dress.

Nothing more was heard of the patient until January 8, when I was called about 9 a.m. I found the boy in bed, complaining of pain in the abdomen, most marked over the right iliac region; he had awakened at 4.30 that morning with a sharp shooting pain in the abdomen, rather to the right side; his mother had tried to ease the pain by application of mustard plasters and the use of hot-water bottles, but with little success.

At the time of this visit there was slight rigidity of the abdominal muscles, also an anxious expression; the temperature was normal; pulse 90. The history of the case from January 2 to January 8 is as follows: The boy got up on January 3; he had taken his meals with the rest of the family as usual, and had gone to school January 4 and 5; on January 6 he had helped his father in the latter's store, and on January 7 he had gone to Sabbath school; his bowels had not moved since the sixth. An enema of soapsuds was ordered, and I told his mother that I would be back to see him in an hour. When I called again the bowels had moved very freely, the patient was resting easily; no pain; temperature normal, and pulse 88; the abdominal muscles were still a little rigid.

I ordered a milk diet, and told them to keep the boy in bed, and to telephone me if there were any recurrence of the pain.

Was called again the same day at 3 p.m. The patient was lying on his back, both legs drawn up, complaining bitterly of pain all over the abdomen, exaggerated slightly in the right iliac region. The abdominal muscles were greatly contracted, hard and board-like; also there was a very anxious expression; his temperature was 99.5°; pulse 100.

I advised an operation at once, telling his parents that it looked very much like a case of appendicitis, with possible rupture.

The boy was removed to the Wheeling City Hospital, and taken directly to the operating table (January 8). Chloroform was given and the patient took the anesthetic very nicely. An oblique incision was made in the right iliac region about 2½ inches in length. Upon opening the peritoneal cavity, more than a pint of a mucopurulent substance, mixed with small particles of fecal matter, began to pour through the wound. By introducing my finger into the abdominal cavity I found that there were no adhesions and that the appendix was normal.

I at once enlarged the opening and pulled out a loop of bowel. This proved to be the ileum, and a large perforated ulcer was found about 2 inches from the lower end. The ulcer was oval in shape—its longest diameter, a little over 1 inch, its transverse diameter a little less than ½ inch. The ileum was greatly inflamed, and was covered with lymph deposits, which were removed with a sponge dipped in normal salt solution. I then flushed out the abdominal cavity several times with normal salt solution, making the cavity as clean as I possibly could under the circumstances, and finally, after the last flushing, left the cavity filled with the saline solution.

Upon closer examination of the ulcer, it was found impossible to close the opening with suture, as the tissue was too necrotic and friable. On the other hand, to excise the ulcer and bring the healthy edges together, I found, would, on account of the ulcer's size, narrow the lumen of the bowel too much, and a resection of the bowel was not advisable, for the patient was too weak to stand the risk of the increased danger of shock, and even of death from so extensive an operation. It was seen at once that a typhoid perforation had to be dealt with, and the question was, how, under the circumstances, was it to be taken care of?

It was determined to make use of the great healing and resistive powers of the peritoneum; accordingly, after the necessary dissection, the ulcer was surrounded with the peritoneum, very fine chromicized catgut being used; this made

the ulcer extraperitoneal, protecting the abdominal cavity, so that any discharge coming from the perforation must come through the wound, and there be taken care of by the dressing.

The skin, fascia, and the peritoneum were then brought firmly together with six silk wormgut sutures—three above and three below the fistulous opening—an opening at each end of the incision being left for drainage. Gauze was used for draining, one strip being placed along the transverse colon, from the upper end of the incision; the second strip was run down deep in the pelvis, extending into the left iliac, from the lower end of the wound, and a small drain was also packed directly down to the ulcer; loose gauze dressings were placed over the entire abdomen, to be changed every three hours.

On leaving the table the boy was in fairly good condition; temperature, per rectum, 102°; pulse, 115. He quickly came out from under the anesthetic, and complained of some pain; morphin, 8 mg. (½ gr.) was then given hypodermically, for the double purpose of relieving the pain and of quieting peristalsis; in three hours the dressings were changed, and found saturated.

Patient passed a very good night; at 10.30 o'clock next morning his temperature was normal; pulse, 105. He complained considerably of tympany; this was relieved by rectal tube; at 4.30 p.m., same day, temperature was 102°; pulse, 115; then hot tea and oroth were given alternately every third hour, the patient retaining the nourishment very well.

On the morning of January 10, 15 cc. (½ oz.) of Hunyadi water was given every hour until four doses had been taken, followed by glycerin enema; the bowels moved nicely. On January 12, four days after the operation, the dressings were dry; the drains were removed, with some little difficulty however, owing to their adhesions to the viscera.

The patient's temperature now ran a mild typhoid course, never going above 103°, reaching that point on January 22. The fistulous opening was closed and the wound completely healed at the end of three weeks. The patient was discharged from the hospital on February 26, seven weeks after the operation.

Conclusions.—1. It is evident that this was a case of typhoid from the start, but not being prepared to make a blood count, I had to do without some of the classic signs. However, the case, at least, shows that advantage is to be gained from early diagnosis and prompt surgical interference without waiting for classic symptoms. 2. That we can have the most serious lesions even in the so-called "mild or walking" typhoid fever cases. 3. That pain, rigidity of abdominal muscles, and quick, tense pulse are three symptoms to be looked for. 4. That the extraperitoneal method is one of the quickest and safest ways of disposing of large perforated ulcers of the intestines, when a resection is not advisable.

THE ENTRANCE AND REMOVAL OF AN UNUSUAL FOREIGN BODY FROM THE BLADDER.

BY

ALBERT P. WEAVER, M.D.,
of Philadelphia.

It has been thoroughly demonstrated in medical literature that foreign bodies of an unusual character are frequently found in the bladder. However a careful search of the literature has resulted in a failure to discover a case similar to the following, which demonstrates how little the laity knows of human anatomy and with what boldness some will interfere with the natural functions of life with no knowledge whatever of the danger of infection to which they expose themselves or their victims.

CASE. S. K., aged 24, married. The patient, a well nourished robust woman, is nursing a healthy child of seven months. On December 4, 1903, at 2 o'clock p.m., the husband called me in great haste stating that his wife was having uterine hemorrhages associated with great pain. On my arrival at the house the husband said his wife had been pregnant about two months, and that they had decided to end this pregnancy. Therefore he secured a "sponge tent," which he described as about the same thickness and one third the length of an ordinary lead pencil, somewhat pointed at one end and covered over with a thin coating of a mucilaginous substance; when moistened with water it became slippery. He said he found the uterus very low down, and without the aid of a speculum or any other instrument he inserted the sponge tent, 10 o'clock p.m., December 3, without any trouble; however, the string which was attached to it was short and disappeared within the uterus. His wife suffered no inconvenience or pain until 14 hours later, when blood appeared accompanied by bearing down pains which became more severe until at last the pain was unbearable and I was sent for. The wife corroborated the statement of her husband; both were apparently ignorant of the crime they were committing and of the dangerous septic infection to which she was exposed. After explaining the possible danger of the woman losing her life and emphasizing the unlawfulness of such an act, they assured me they would assume all the responsibility

¹ Reported to the Ohio County, W. Va., Medical Society, at a meeting held February 26, 1904.

and allow me to notify any authorities I might deem necessary, and I therefore took charge of the case. On examination I found bright red blood coming apparently from the vagina; two or three heavy napkins had been saturated. The commode at the side of the bed contained over two quarts of blood and urine, which had been passed during the two hours previous. Intermittent pains appeared from five to eight minutes apart. Digital examination showed the uterus well up in the pelvic cavity and difficult to reach with the end of the index finger. The os was tightly closed, firm but rather soft to the touch. It was in normal position and freely movable, with all the indications of a 2½ or 3 months' pregnancy.

No hemorrhage was coming from the uterus and I therefore again questioned the husband as to the manner in which he had used the appliance.

He insisted that the womb was low down, and that he had made the insertion without any difficulty. I strongly suspected that he had mistaken the opening of the urethra for the uterus, and close examination showed the blood was coming from the urethra. With a soft rubber catheter about one ounce of bloody urine was drawn. The catheter passing through the urethra caused no pain or inconvenience, but as soon as it entered the bladder violent pains came on, with severe bearing down sensation, forcing from the urethra more blood and urine. This verified the diagnosis that the sponge tent had been inserted through the urethra into the bladder. Its presence there between 15 and 16 hours, had produced an aggravated cystitis. Temperature, 101° F. Pulse, 90.

Immediate preparations were made for its removal. Dr. J. L. Dukes anesthetized the patient with ether. The urethra was dilated sufficiently with an ordinary pair of uterine dressing forceps to admit the entrance of the little finger. Dilatation was gradually increased until the index finger could be inserted into the bladder, where a rough mass could be plainly felt. By working the finger around this mass it could be readily moved, but each time it was moved the walls of the bladder would contract, forcing out blood mixed with urine.

The index finger pressed tightly against the mass, prevented it from changing its position when contractions of the bladder occurred. The uterine dressing forceps were now passed into the bladder alongside of the finger until the foreign body could be grasped. The finger was removed, and with slow and steady traction effort was made to remove the foreign body, but this could not be done, as small pieces would break off, showing it to be a real sponge. After several unsuccessful attempts the urethra was further dilated and the middle finger was forced through the urethra, making a complete dilation. The uterine dressing forceps were again passed into the bladder and a full grasp of the foreign body secured; by steady and firm traction with a twisting motion the complete foreign body was pulled out. It consisted of a cone-shaped piece of coarse sponge, 7 cm. (2½ in.) in length. Width at base, 4 cm. (1½ in.). Width at apex, 2 cm. (¾ in.). It was saturated with blood and urine, and emitted an exceedingly offensive fetid odor. Near the base end was attached a white silk cord.

After its removal the bladder was thoroughly explored by means of the index finger, and then thoroughly washed out with a hot 10% solution of boracic acid. This operation took 25 minutes. The patient was put to bed. Considerable vomiting occurred from the effects of the ether. For three days the bladder was washed out twice in 24 hours with the boracic solution.

For 48 hours there was incontinence of urine, which gradually subsided, until at the expiration of four days there was complete control of the bladder. On the fifth day the patient was up attending to her regular household duties. Frequent urination continued for 10 days, but at the expiration of two weeks complete recovery was established. After the expiration of over five months no cystitis or irritation of the bladder has occurred. The patient is in good health, and pregnancy is going on in normal condition.

EXTRACTION OF A BULLET, LOCATED BY THE RÖNTGEN RAYS, FROM THE ORBIT.¹

BY

HOWARD T. HANSELL, M.D.,
of Philadelphia.

On February 15, 1904, Miss S. attempted suicide by shooting. The bullet from a 22-caliber pistol passed through the temporal muscle and the temporal bone of the right side. The woman fell to the floor and as soon as practicable was sent to a hospital in an ambulance. Neither immediately after the injury nor at any later time was she unconscious. After a two weeks' stay in the hospital she came unaccompanied to my office. I found a small blue-colored indentation in the skin 1½ in. posterior to the bony margin of the orbit and on a line horizontal with its center. There was complete paralysis of the third nerve and total loss of vision, but no impairment of the cerebral faculties and no paralysis. The eyeball was turned down and out, almost completely immobile, deeply injected, painful to the touch and no view of the fundus was obtainable on account of hemorrhages into the vitreous. I assumed that

the bullet had perforated the external orbital wall and was lodged in the posterior portion of the orbit, the nerves, blood-vessels and possibly the muscles of the eye having been destroyed either by the bullet or by the depressed fragments of the temporal bone, and that in order to extract it an incision should be made through the temporal muscle, and the bone trephined. The assumption was generally incorrect. By means of a radiograph and the localization method of Dr. W. M. Sweet, the position of the bullet was demonstrated to be between the posterior part of the ball and the inner wall of the orbit. An incision was made through the upper lid and the posterior tis-

sues between the eye and the roof of the orbit divided, making a wound large enough for the insertion of the little finger, until the designated site of the bullet was reached. The hemorrhage was insignificant since the course of the incision was such that the large vessels were avoided. The bullet was freed from the surrounding tissues and removed with the forceps. A strip of iodoform gauze was inserted into the wound and allowed to remain for 24 hours when the edges of the incision in the lid were sutured. Healing was prompt and the patient was discharged on the third day. Several weeks have elapsed since operation. The eye has regained much of its former

motility, the drooping of the lid is decidedly less, the injection has mostly disappeared and the pain has subsided.

The radiograph shows not only the position of the bullet but also the presence of 3 or 4 minute fragments lying in the orbit posterior to the globe. These are probably innocuous and will be allowed to remain.

The pistol was held in the right hand and its barrel directed forward and slightly upward. After having entered the orbit the bullet struck the roof of the orbit with insufficient force to penetrate it and glanced off, finally lodging in the position from which it was extracted.

ORIGINAL ARTICLES

SURGERY OF URINARY TUBERCULOSIS IN WOMEN.*

BY

GUY L. HUNNER, M.D.,

of Baltimore, Md.

Associate in Gynecology, The Johns Hopkins University.

In a recent paper on "Tuberculosis of the Urinary System in Women,"† I reported 35 cases which have occurred in the service of Dr. Howard A. Kelly and his associates in Baltimore.

That paper was devoted chiefly to the questions of diagnosis. These must likewise be emphasized in this paper for there can be no true surgery of the urinary tract without painstaking and in the majority of cases, accurate diagnosis. In addition I wish to give you some idea of the present status of the surgical technic as evolved in the work on these 35 cases. And finally a review will be given of the results of this surgery with reference to wound healing, cure of the local disease, and effect on the general health of the patient.

Etiology and Pathology.—All of our cases were in women, and their average age at the time of treatment was 32½ years, the average duration of symptoms having been 4½ years.

Expressed in decades the classification of ages at the time of treatment is as follows:

Ages.	Number of Cases.
10 to 19	1
20 to 29	14
30 to 39	12
40 to 49	6
50 to 59	2

Considered from the age of onset the majority of patients were under 30 years of age. Twenty-two of these were at the Johns Hopkins Hospital and it is interesting to note that while a fifth of the gynecologic patients at that institution are colored women, and while the colored race is peculiarly susceptible to tuberculosis in all its forms, medical and surgical, all of these patients were white women.

The family history was recorded in 28 cases, and in 13 of these there was noted tuberculosis in some member of the family.

Several patients had foci of disease elsewhere. One patient had suffered from a knee-joint inflammation, probably tuberculous in nature, after her urinary symptoms were established. One patient had had tuberculous right submaxillary glands removed 2 years before her bladder symptoms began. One was operated on for suppurating axillary glands 2 months after her kidney operation. One patient had been operated on for pelvic inflammatory disease, probably of a tuberculous character, 3 years before her symptoms began in the kidney. One patient has had her pelvic organs removed for tuberculosis since her nephrectomy. Five patients not of the above number had evidence of former or active lung involvement.

The operation was on the right side in 17 cases and on the left in 18 cases.

All of the cases showed the chronic caseous form of nephritis in contradistinction to the acute diffuse miliary type. All grades of nephritis were seen varying from the kidney with multiple small nodules or abscesses, with much of the kidney still functioning, to the cases of pyonephrosis with complete destruction of the secretory substance. Several were smaller than normal and largely occupied by fibrous tissue. One kidney was converted into a multilocular cystic mass.

* Read before the meeting of the Southern Surgical and Gynecological Association, Atlanta, December, 1903.

† This paper was published in the January number of *The Johns Hopkins Hospital Bulletin*, and in the January number of the *Maryland Medical Journal*. The reader is referred to these journals for a brief summary of the history of each of these cases. The designation by case number in this present paper refers in each instance to the cases as cited in the former paper.

When kidney and bladder are diseased it is impossible to say in which organ the disease was primary. There was no cystoscopic note in 4 cases. The bladder was normal or showed simple redness and swelling of the ureteral orifice, thus indicating a kidney origin, in 13 cases. The bladder was ulcerated or showed distinct inflammation about the ureteral orifice in 18 cases. Excision of the ulcerated areas in one of these cases resulted in cure and the excised tissue was not tuberculous. Two bladders healed rapidly on ordinary cystitis treatment after excision of the diseased kidney, and one healed spontaneously within 6 months. One bladder healed before removing the kidney, on having a vesicovaginal fistula made and receiving daily irrigations. One patient with slight inflammation about the ureteral orifice has had no treatment and no symptoms since the kidney extirpation. I would class these 6 cases among those whose disease was primary in the kidney. One patient died 11 weeks after operation from apparent failure of the other kidney. Her disease may have been primary in the bladder. This leaves 11 patients to be accounted for out of the 18 who were known to have bladder lesions. All of these 11 patients still have some bladder symptoms and four are known to have ulceration of the bladder. Nine of them have had more or less thorough bladder treatment. This persistence of the bladder lesion after removal of the diseased kidney and in spite of treatment, is good evidence, I think, that these 11 patients have tuberculosis of the bladder.

Was the disease primary in the bladder in these 11 cases? It may seem significant that the symptoms first began in the bladder in 8 of these. But we can no more draw dogmatic conclusions from the history than from the pathologic conditions. Three of the patients with extensive kidney lesions had complained only of bladder symptoms, over periods of 13 months, 3½ and 9 years respectively. Of the 13 cases which the cystoscope showed to have normal bladders, 10 had suffered with bladder symptoms at some period, and the earliest symptom was in the bladder in 4 cases. In my former paper I stated "while the symptoms first noted were in the bladder in 17 out of 34 of the cases, a close scrutiny of the histories and comparison with the clinical and pathologic findings convince me that in by far the great majority of cases, urinary tuberculosis in women originates in the kidney. With the widest margin in favor of primary bladder infection, I have classed but 5 of the 35 cases under this heading." On more careful investigation I am still less inclined to consider any of these cases as cystic in origin.

In 30 cases reported by Israel he thinks that 8 may have been of the ascending type, but his cases include both sexes, and we would expect the ascending form more frequently in men. In favor of descending infection is the fact that of the 11 cases of our series showing probable bladder tuberculosis, in 8 the lesion was local and confined to the region of the ureteral orifice on the affected side.

I have seen but 2 cases of urinary system tuberculosis in which the lesion was apparently confined to the bladder, and 1 of these was a case of direct extension of the disease through the bladder wall after operation for pelvic tuberculosis.

Of the 13 patients with normal bladder, only four had any evidence of tuberculosis outside the kidney and ureter. There is scarcely any doubt that in addition to claiming the kidney as the most frequent primary seat of tuberculosis in the urinary system, we may also say that it is not infrequently the primary seat of tuberculosis in the body as a whole. This is an important conclusion if we are to consider kidney tuberculosis a surgical disease.

Symptoms and Diagnosis.—Symptoms may be entirely wanting, the patient complaining only of "blood in the urine" (Case XIII) or of a "thick ropy urine" (Case VI). From a comparison of clinical histories and patho-

logic findings there can be but little doubt that a characteristic of the disease is its latency, hence the slow onset of symptoms in most cases, as also the sudden onset like an attack of renal calculus in other cases, where the first symptom is probably caused by the blocking of a thickened ureter with a bit of caseous material or blood-clot from the kidney.

Pain.—In 17 of the cases the first symptoms were referred to the bladder. Eleven of the patients complained first of a discomfort in the back, varying from a slight soreness or fullness, or stiff feeling, to all grades of backache. Five patients gave a history of acute onset, with renal colic, in which the first or early attacks of sudden violent pain were accompanied by nausea, vomiting, chills, and fever. Pain in the course of the ureter is not uncommon.

Bladder Symptoms.—These were present at some time in the course of the disease in 31 out of 34 cases in which a history was recorded. In 3 of the cases the entire local symptoms had been confined to the bladder. The symptoms vary from a slight discomfort, with frequency of urination, to the most excruciating pains. The most severe pain may arise during the act of voiding, giving rise to strangury and bleeding. Reflex symptoms from the kidney or ureter are very common, as seen from the fact that 31 out of 34 of these patients had bladder symptoms, while only 18 had bladder lesions. These reflex symptoms usually take the form of a constant desire to urinate. The frequency may occur only during an attack of kidney colic, or during the attack there may be severe spasmodic pain referred to the bladder. Pain referred to the urethra or to its external orifice is not uncommon.

Urine.—Polyuria is said to be a not uncommon feature in the early stages. I find that the average patient does not differentiate between the frequency incident to the early irritation and an actual increase in amount of urine. Oliguria is common in the later stages of the disease, unless the patient is drinking large quantities of fluids.

Hematuria.—It is probable that blood is present at some stage in every case. Ten patients had noticed blood in the urine; 5 histories state that no blood had been noticed, while in 20 cases there is nothing said about this point in the history. In 6 of these 20 cases, however, blood was found microscopically after their admission to the hospital. Blood, unless carefully looked for, may be easily missed in the routine microscopic examination, because of the large number of pus elements. When blood was noticed by the patient it was generally in the early history of her symptoms. Our earliest case was one in which hematuria for 2 months had been the only indication of disease. After the bladder is involved in ulceration, blood can always be found microscopically, and I have seen it profuse from this source. Cases of serious hemorrhage from advanced kidney disease are reported in the literature. Of the 10 patients who had noticed blood, 8 patients were examined cystoscopically, and all but one of these had ulceration of the bladder. König¹ says that before the foci of disease communicate with the pelvis there may be absolutely no sign of disease in the urine. We would expect, however, in all cases to find some microscopic evidences of disease, such as blood, pus, tubercle bacilli, or casts, before there is actual communication with the pelvis.

Pyuria.—Pus was present in every case. With blocking of the diseased ureter the urine may be clear. The amount of albumin seemed to vary largely with the varying quantities of pus and blood. Casts, hyaline or granular, or both varieties, were reported in but 3 cases. I believe careful examination of fresh specimens would reveal casts more frequently.

Urea Tests and Cryoscopy.—Urea tests for the two sides were recorded in but few cases. This test always shows a marked diminution of the urea percentage on

the diseased side. Cryoscopy was tried in two of these cases and yielded striking results.² In Case XXIV the urine catheterized from the diseased side showed a freezing-point of -0.49° , while a mixed specimen froze at -1.89° . In Case XXXI the urine from the diseased side congealed at -0.625° and that from the good kidney, collected through the bladder, at -1.74° . The freezing point of the blood in these 2 cases was normal, or -56° . In the average case we can make an accurate diagnosis without cryoscopy, but in case of disease of both kidneys the freezing test for the blood and separate urines will prove of great value in determining whether there is approximate renal sufficiency, and the relative value of the 2 kidneys; in other words, whether any operative interference is justifiable, and if so, whether one or both kidneys should be operated on, and the nature of the operation.

Reaction.—The urine was acid in every case, thus demonstrating that the popular textbook idea of alkaline pyuria differentiating a cystitis from a pyelitis will bear revision.

Bacteriology.—Slant agar tests were made in many of these cases, but unfortunately the records are preserved in but 9 of them. Of these, 4 were sterile, 4 contained a colon bacillus growth, and 1 a growth of streptococcus. From my bacteriologic observations I would say that the rule in tuberculous pyuria is to find sterile urine when testing on our ordinary media. The mixed infection in all our cases but one has been by *Bacillus coli*. It is probable that the acid urine present in tuberculous cases limits the varieties of bacteria that can exist in the urine to the acid producers. On the other hand, the presence of colon in most of these mixed infections of our series may be a coincidence, for we know that about half of all cystitis infections are by the colon group.

Demonstration of the presence of tubercle bacilli is the only manner in which we can make a positive diagnosis. This is done by finding the bacilli in the urine or by causing tuberculosis in the guinea pig by urine inoculation. Tubercle bacilli should be demonstrated in practically every case. One or two slides made from the centrifugalized urine should be examined daily for at least a week if necessary. In this time there is almost certain to be a breaking down of tuberculous foci and the precipitation of bacilli. This is a far less laborious and more certain method than that of examining a multitude of slides in one day. I allow the catheterized specimen to stand in a conical glass for a few hours and then pipet about 5 cc. to 10 cc. from the bottom for centrifugalization.

The differential stain should always be used. We have heretofore considered that drawing a catheterized specimen from the bladder excludes the smegma bacillus. But I have had an experience only the past summer that demonstrates the necessity of a differential stain in all cases. From a bladder showing universal ulceration apparently secondary to disease of the right kidney and ureter, I obtained by catheterization a specimen of urine on two different days, each specimen showing by the Gabbett method of decolorizing, a number of organisms retaining the typical stain, but being somewhat plumper in form than the tubercle bacillus. No evidence of tuberculosis could be found in the excised kidney and ureter, and after a vesicovaginal fistula and irrigations for 6 months I was able to close the fistula over a bladder with normal mucous membrane. I do not believe this could have been a tuberculous bladder. One case (XV) of our series makes me question whether even the differential stain can be relied upon. Her physician, one of the most scientific in New York City, had repeatedly found organisms corresponding to tubercle bacilli after the differential stain. After the patient's admission to the hospital, the ward interne, using the differential stain, found similar organisms in a catheterized specimen from the bladder. These specimens were examined by the hospital pathologist, Dr. N.

McL. Harris, and considered by him as undoubted tubercle bacilli. But most thorough search of sections taken from every portion of the necrotic and sclerotic kidney failed to show any tissue with evidence of tubercles. This patient's urine is normal at present, showing that the bacilli in question were in all probability not from the remaining kidney. Case XII had a similar sclerotic kidney, in which there was but one small caseous focus in which tubercle tissue could be demonstrated. Every other portion of the kidney showed chronic granulation tissue, but no areas typical of tuberculosis. Knowing that we may have complete obliteration of the tissue typical of tuberculosis I have depended upon the differential stain in Case XV, and upon this evidence only has this case been included in this series. Future work may show that the differential stain cannot always be depended upon.

In 22 cases on which a note is made as to search for tubercle bacilli 15 yielded positive results. In one other case bacilli were not found, but inoculation of a guinea-pig with urine from the affected side resulted in death of the animal from tuberculosis. Of the 7 cases in which a negative note is recorded there was usually but one effort made to find the bacilli. Of the 15 positive cases 8 were specimens catheterized from the bladder and 7 were specimens taken directly from the kidney. In one of the latter, bacilli were found in specimens catheterized from either kidney. As one would expect, bacilli seem more plentiful in the specimens taken directly from the kidney. If the guinea-pig is used for purposes of diagnosis it is well to inject at least 3 pigs, 1 intraperitoneally, and 2 subcutaneously in the flanks. A catheterized specimen should be taken into a sterile receptacle and centrifugalized as soon as possible under approximately aseptic precautions; and the centrifugalized sediment should then be used for inoculation before there is time for development of contaminating organisms, for the guinea-pig is peculiarly susceptible to infection and is likely to die early if organisms other than the tubercle bacilli are introduced. If a specimen of the diseased bladder tissue can be curetted a portion of this may be introduced into the flank of a guinea-pig while the remainder is kept for microscopic examination.

Tuberculin Reaction.—If tubercle bacilli cannot be found and one has not time to wait for a guinea-pig test, the tuberculin reaction may be tried. This is uncertain in cases with fever but for suitable cases we have learned to place considerable confidence in its indications.

Cystoscopy.—Examination of the bladder with the cystoscope is of great service in diagnosis. Very often there is no change in the bladder except a slight redness and puffiness of one ureteral orifice. Again, there may be local changes of considerable degree in the bladder mucosa about the orifice of the affected side. If the bladder is universally inflamed one may still be positive about the diseased kidney from the fact that one ureter is thickened and shortened, and its orifice, instead of standing out on a mons ureteris, is located in a saucer-like depression of the bladder wall.

Catheterization of the Kidney.—In my former paper I stated my views against the catheterization of a supposedly healthy ureter and kidney in the presence of disease of the other kidney. Much information may be gained regarding the character of the urine and the rate of flow by simply placing the patient in the Sims or the knee-chest posture and watching the ureteral orifices. More can be learned by catching the urine for examination as it leaves the ureters. Dr. Kelly has a speculum with an oblique end which is more easily held to cover the ureteral orifice than is the ordinary circular end speculum. Our usual method of separating the urine is to catheterize the diseased side and have the patient take the dorsal position. The bladder is then thoroughly washed out and emptied. The urine which collects in the bladder while the catheter drains the diseased side represents the better side. If the entire bladder is dis-

eased and there is but one thickened ureter and the symptoms are confined to the corresponding side, I think it entirely justifiable to catheterize this side, even though the regions of both ureteral orifices look the same. With these conditions and failure of the catheter to enter the thickened ureter, I would abandon an attempt at diagnosis through the bladder and depend upon a preliminary incision over the supposedly better kidney before attacking the side known to be diseased. It must not be forgotten that both kidneys and the bladder and only one ureter may be diseased. I have seen one such case in which a much hypertrophied and diseased left kidney and ureter were removed, dependence upon the integrity of the right kidney being placed upon the fact that the patient was in fair health, had a normal right ureter, and a right kidney apparently normal on palpation. The bladder was so diseased that neither ureteral orifice could be found. In a week the patient died, having passed no urine; and, on investigation, the right kidney was found to be a multilocular cystic mass with one caseous area in its cortex, while the ureter was normal.

I have used the Harris segregator and the Downes modification of this instrument, and am not favorably disposed toward them. It is only necessary to use the hand of a rubber glove as a receptacle in order to demonstrate how easily fluid leaks around the lever ridge at the bifurcation of the catheters; and a thickened, diseased bladder floor is by no means as pliable as this rubber glove basin. Cathelin's rubber diaphragm separator is a more practical instrument, but this, again, cannot be depended upon in the cases in which it is most needed, for in a roughened, uneven bladder floor the wire rim holding the rubber diaphragm must ride over the more projecting nodules and allow the intermingling of the urines in the sulci beneath the wire.

Tumor.—The absence of tumor formation is not of diagnostic importance. In women, the size of the right kidney can usually be ascertained, while the left kidney may be considerably enlarged and still not be palpable. A priori, one would expect the largest tumor in a case with perirenal abscess or collection of pus in the capsula adiposa. None of our cases showed this condition. A note on palpation is recorded in 26 of our cases. In six of these there was visible or very large palpable tumor. Five of these were either large pyonephrotic or multiple abscess kidneys, while the sixth was a kidney with caseous lobules opening more or less freely into the kidney pelvis. In this sixth case I had noted repeated variation in the size of the kidney. With elevation of temperature, chills, and pain in the left lumbar region, the kidney became distinctly larger. In 10 of the 26 cases the note says the kidney is enlarged. In five the kidney was palpable, but of normal or diminished size. In five the kidney was not palpable. Enlargement is often due to perinephritis of a nonpurulent character. The capsula adiposa becomes inflamed and thickened, and forms a dense cartilage-like shell about the kidney. The kidney itself under these conditions may be enlarged, normal, or greatly diminished in size.

Ureter.—A note on palpation for ureters is made in 19 cases. In 1 case the ureters are said to be free from tenderness, nothing being said as to palpability. In 18 cases one or both ureters are described as palpable, and the usual note is that they are thick and tender. The ureter can generally be palpated as it crosses the pelvic brim, and in the pelvic portion it may be palpated through the vagina and particularly through the rectum. Palpation of the kidney often causes pain and a desire to void urine. These symptoms are more frequently elicited on palpation of the ureter. The base of the bladder may be thickened and tender, particularly on the affected side, and its palpation may cause referred pain in the urethra.

General Condition.—It is surprising that a patient may carry a badly diseased kidney and still possess good

nutrition, a high percentage of hemoglobin, and to all appearances be in perfect health. Most patients however show some anemia and give a history of having lost weight and strength. Some of our patients who are in excellent health today were brought to the hospital on a stretcher and were most hopeless looking beings. Lack of drainage of the infected kidney, and bladder symptoms disturbing the patient's rest at night, are the chief causes of a cachectic condition. The temperature in many of our cases was normal on admission and remained normal until operation. In others there was slight fever, often of the hectic type. In 7 cases the temperature was 103° F. or higher, and one patient with a large pyonephrosis had a temperature on the day of admission of 106.2° F.

Treatment.—If the disease is one-sided, as it is in about 90% of cases when seen reasonably early, operation without delay is indicated, for of 100 patients dying without surgical intervention, 51% are found to have double-sided disease.³ As Israel points out, the infection of the second kidney is generally a matter of years, for the disease is usually diagnosed and operated upon at a late period, and is still found to be one-sided in 9 out of 10 cases. In our series the operation was at a period 4½ years after the symptoms began and the disease was probably unilateral in 92%. We know from our pathologic specimens that it is possible for tuberculous disease of the kidney to heal. We know from clinical experience that persons may live for years with both kidneys diseased. But we know also that one may live in comparative health for years with but one kidney, and that the seat of tuberculosis. If previous cryoscopy has shown renal sufficiency and a wide difference in the value of the two kidneys it is indicated to remove the poorer kidney if this be the seat of predominating symptoms. Occasionally one will find a portion of the poorer kidney in a condition of apparent health. In such a case the question of a partial resection must be considered. Partial resection is the operation of choice in the rare cases of double kidney with double pelvis and ureter, in which but one segment of the kidney and but one ureter show disease.

Nephrotomy.—Simple incision and drainage is no longer used as a curative measure and is not justifiable unless for special reasons, which make nephrectomy inadvisable. As already inferred, both kidneys may be so extensively diseased that life would be precarious if either were removed, and yet one kidney only may be the seat of repeated distention with pus, causing fever, chills, loss of appetite, loss of rest, and causing secondarily a profound cachexia. In such a case free incision and permanent drainage of the more diseased kidney is indicated. Second, the patient may be too ill when first seen to bear a nephrectomy. Opening of the large pus kidney or of a perinephritic abscess in such cases is the only operation advisable, and this may be done under local cocaine anesthesia or under general anesthesia with nitrous oxid gas. After the patient improves sufficiently, complete nephrectomy or intracapsular enucleation of the kidney may be done. Four of our patients had nephrotomy with a later nephrectomy. The removal of the kidney in three of these cases was accomplished by intracapsular enucleation, these being the only cases of the series in which this expedient became necessary.

Nephrotomy with drainage was the only operation in 3 of our cases. Two of these had evident involvement of the opposite kidney, and died from this cause, Case IV within 11 weeks, and Case V after 2 years. Case XIV improved rapidly during 6 weeks in the hospital, and then insisted upon returning home. She is the only patient in the series whose ultimate condition we have been unable to learn. Generally in cases of large pyonephrosis or of perirenal abscess the greatest prominence is situated in the anterior flank region. Given, a tumor in this region, and inability to make a diagnosis between gallbladder, kidney, or other point of origin, it is prob-

ably indicated to approach the tumor over its most prominent portion. If the peritoneum is entered and the tumor found to be renal in origin, this exploratory wound should be closed, and the incision and drainage made in the lumbar route.

Nephrectomy.—With normal bladder, and the ureter showing no macroscopic changes, conservative surgery calls for simple removal of the tuberculous kidney. In such cases the renal end of the ureter may be tied with silk or catgut, a clamp set above the ligature, and the ureter burned across with the cautery. Or, still better, the cautery clamp may be used to sever and seal the ureter. If the kidney has been removed without contamination of the tissues, the wound is closed for per primam healing, but if the kidney has ruptured and contaminated the field, or if one is not reasonably certain that the ureter is free from tuberculosis a small iodoform gauze drain is inserted. Our series includes 9 cases of nephrectomy (VI, XIII, XV, XVII, XVIII, XX, XXI, XXVIII, XXXIII). Case XXI died 6 weeks after operation with evident involvement of the opposite kidney. The remaining 8 patients are living, and the wounds have healed in all but three—Cases XVII, XXVIII, and XXXIII.

Nephrectomy and Partial Ureterectomy.—By partial ureterectomy we generally mean the removal of the ureter down to the pelvic brim, or as far as it can be followed through the wound made for the kidney extirpation. The term is used as well for those cases in which but a few centimeters are removed for microscopic examination. I believe the operation should be confined to the removal of 5 cm. or 6 cm., for if the ureter is not diseased nothing is gained by following it lower, and if it is diseased, it is better to bring its upper end out on the skin surface (as suggested by Israel) than to leave a long tract for infection between the end of the ureter and the skin wound. If future ureterectomy through an inguinal wound is contemplated, a few centimeters of ureter to be released above the pelvic brim will not materially complicate the operation. Nephrectomy and partial ureterectomy were done in 7 of our cases. They are all living, and the wounds have all closed, except in Case XXIV, whose wound is still slightly open after 22 months.

Nephroureterectomy.—If the ureter is involved, as it is in the majority of cases when the patient comes for treatment, the ideal operation is the complete removal of both kidney and ureter. Dr. Kelly has developed a splendid technic in this operation, and I shall enter with some detail into the methods now in use by him and his associates. The operation was formerly done through what one patient describes in her letter as "an 18-inch incision," in other words, the patient was "quartered." We now use 2 short incisions; the operation is usually extraperitoneal, and may be done in favorable cases without cutting a muscle. The patient is placed in a prone or semiprone position with an inflated rubber bag (Edebohls') well up under the lower thorax. The lumbar incision begins in the angle formed by the erector spinæ muscle and the last rib, and is carried downward and forward 8 cm. to 12 cm. in a line about parallel with the direction of the twelfth rib. The incision is carried through the skin, subcutaneous fat, and deep fascia, and exposes the latissimus dorsi muscle whose anterior border crosses the incision about midway. This muscle is grasped by skin retractors and drawn posteriorly, thus exposing the posterior border of the external oblique. The border of the external oblique is drawn anteriorly and the border of the internal oblique is exposed, together with the lumbar fascia, as it gives origin to the transversalis muscle. We have thus, without cutting a muscle or any important nerve or vessel, exposed the superior lumbar trigonum, a triangular fascial area with its base forming the arcuate ligament just inferior to the twelfth rib. An artery forceps is plunged through this fascia, and on spreading its blades the retrorenal fat appears through the opening. This

lumbar fascia is now cut or torn until its opening is of the desired dimensions.

If the inflammation is confined to the kidney this organ is usually seen sliding up and down in the wound, and after breaking through the capsula adiposa, the kidney is delivered with more or less ease, according to its size. If the capsula adiposa is the seat of inflammatory disease, the kidney may be anchored deep in the wound and be hidden from view until this outer capsule is dissected free from the capsula renalis. In some cases with perirenal thickening the kidney is best delivered with its thickened capsule intact; in others the fatty capsule must first be stripped and the kidney then delivered. In still other cases, particularly in those where the kidney has been previously drained, the capsula adiposa has become so thickened and adherent that it is impossible to deliver the kidney, and one must first cut through both the fatty capsule and the thickened capsula renalis and then do an intracapsular nephrectomy.

It is sometimes an advantage in the adherent cases to first sever the ureter. I have found it an excellent plan in these difficult cases to resect the twelfth rib, in fact, this is my rule in tuberculous kidney cases. In such cases the preliminary incision is made directly over the twelfth rib, beginning somewhat more posterior than the incision just described, and the latissimus dorsi muscle is divided instead of retracted. This enables one to approach the inflammatory field by a more direct route, exposes any adventitious vessels, and greatly facilitates the control of the normal vessels after the kidney is delivered. To control the vessels it is possible in most cases first to strip them entirely of the fat about the hilum and to expose them for separate ligation. With a blunt instrument, best with a serrated spatula, one strips down the fat alternately on the anterior and posterior surfaces and then ties the vessels from the posterior exposure. When working on the right side the surgeon should bear in mind the shortness of the right renal veins and the proximity of the inferior vena cava. After freeing the kidney, the ureter is dissected loose down to the brim of the pelvis. The ureter is then clamped at about its isthmus, and a ligature is placed somewhat below the clamp. The ureter is cut or burned through with the thermocautery, and its mucosa above the ligature is carefully cauterized. The clamp and ligature are both dispensed with and a clean field insured by using the Downes cautery clamp. If the operation has progressed to this point without contamination of the field by tuberculous material, the wound may be entirely closed and the patient turned to the dorsal position for the ureterectomy.

The ureter incision is made parallel to and about 5 cm. above Poupart's ligament, beginning about opposite the anterior superior spine of the ilium and ending near the sheath of the rectus. With a little experience this incision can be made so that its ends lie between the main branches of the superficial circumflex iliac and the superficial epigastric vessels, so that one does not have to clamp or tie a vessel in reaching the muscles. The peritoneum is now exposed by cutting through the muscles or by separating them layer after layer in the direction of their fibers. On reaching the peritoneum this is pushed toward the median line, thus exposing the external iliac vessels running along the border of the true pelvis. Following these vessels toward the median line by sight, or preferably by touch, the ureter is found as it dips over into the pelvis at about the junction of the external with the common iliacs. The ureter goes with the peritoneum and should be sought as the peritoneum is being pushed medianward. Occasionally the periureteral thickening holds both ureter and peritoneum in firm union with the fascial sheath of the iliac vessels. Having found the ureter at this point one reaches above the pelvic brim for the upper end, which has already been loosened from above. Grasping the freed upper end, the ureter is gently torn from the

peritoneum in front and from the fascial attachments behind. Great care must be exercised in freeing a strongly adherent ureter from the iliac vessels; if necessary, a portion of the periureteral tissues are cut free and left with the vessel sheath. If the ureter is densely adherent to the peritoneum, it is best to free it by a sharp knife dissection, thus avoiding ragged tears into the peritoneal cavity. At times the deep pelvic portion of the ureter, or the broad ligament portion, is surrounded by a dense mass of thickened fat. If the patient is in fair condition this should be removed down to the bladder wall, although the uterine vessels of the corresponding side will have to be sacrificed. In the average case one can sever the ureter at the bladder without permanent injury to the uterine vessels. The inguinal wound is completely closed or it is drained, according to the conditions of the individual case.

Our list comprises 13 nephroureterectomies (Cases I, II, III, X, XII, XXII, XXV, XXVI, XXVII, XXIX, XXX, XXXIV, XXXV). These patients are all living, and their wounds healed promptly, except in Case XXV, whose wound still opens at times after 14 months.

Nephroureterocystectomy.—Resection of a diseased portion of the bladder, together with the ureter and kidney, was done in 3 cases. In Case XVI Dr. Kelly removed the left kidney through a lumbar wound, and the left ureter and a section of the bladder through a suprapubic median transperitoneal incision. The abdomen was closed without drainage. On the fourteenth day symptoms of general peritonitis began, there was no further passage of urine through the urethra, and the patient died on the fifteenth day.

In Case XXXI, I removed a small area of the diseased bladder with the urethra, and another ulcerated area 3 cm. or 4 cm. in diameter from the vertex of the bladder through a suprapubic extraperitoneal incision. The urethra and urethrovesical region were removed through the usual extraperitoneal inguinal incision without tying the uterine vessels, these being simply displaced forward with a curved spatula. A cone of the bladder was drawn well into the wound, and before the bladder was opened, interrupted catgut sutures were set beyond the area to be resected. After removal of the urethrovesical area these sutures were easily tied. A small drain was inserted to the bladder suture, but there was no leakage. The patient is in excellent health, and free from bladder lesion, after almost 2 years. I performed a similar operation in Case XXXII, removing a portion of the bladder with the ureter without injury to the uterine vessels. In this case, however, the ureter was densely adherent to the peritoneum throughout the pelvis, and the patient's condition necessitated rapid work, resulting in a free tearing of the peritoneum. She had disease of the opposite kidney, and the operation was undertaken only because of the repeated blocking of the ureter, with resulting high fever, severe chills, and profound prostration. The operation of safety in her case would have been simple nephrotomy, but her social conditions were such that she desired to take extreme chances and be rid of after-treatment. For this same reason I closed a vesicovaginal fistula which had been previously made for treatment of a cystitis. The patient showed signs of uremia from the time of operation, and died on the sixth day. Her death may have been hastened by peritonitis due to leakage from the bladder wound, for after loosening the drain on the fourth day, less urine was collected through the retention catheter. Several criticisms should be made regarding the conduct of this case. In the first place, the surgeon should not allow the wishes of the patient or her friends to carry him beyond what seems the only safe course in operating. This patient might still be alive if nephrotomy had been done. Second, in view of the resection of a portion of the bladder, the vesicovaginal fistula should have been left for drainage of the bladder. Third, in any similar case in which the peritoneum is opened, the

packing between the bladder and the intestines should be generous in amount, and should not be disturbed until firm intestinal adhesions are formed.

Treatment of the Bladder.—I am not in favor of a partial resection of the bladder at the primary operation except in rare instances. If the disease is confined to the immediate vicinity of the ureteral orifice and tubercles can be seen in the ulcerated area, and if the nephroureterectomy has progressed without opening the peritoneum, I think the bladder operation may be added. Or a vertex ulcer, situated where it can easily be reached by an extraperitoneal incision, may be removed. We know that some cases of bladder involvement are not specific, and that they clear up after removal of the diseased kidney. In Case XXXI, I felt positive that the periureteral inflammation and the deep ulceration in the vertex were tuberculous, but the microscope showed them to be non-specific, and I doubt not that the cystitis would have quickly healed under ordinary methods of treatment. In Case XXIV I felt certain, from the appearance of the bladder, that it was tuberculous; but the entire disease, covering a third of the organ, has healed in 6 months without treatment.

I cannot agree with Motz,⁴ of Paris, who thinks there is a tendency to spontaneous healing in tuberculosis of the bladder. He reports 8 cases of cure, six of which healed without vesical treatment, four after the removal of a tuberculous kidney. He bases his diagnosis on the existence of cystitis symptoms and the presence of tubercle bacilli in the urine, cystoscopic examination apparently having been made in but 1 case. Many of our cases with bladder symptoms and tubercle bacilli had perfectly normal bladders. When in the cystitis cases we get healing without treatment, or after the ordinary methods of treatment, we set them down as cases of secondary cystitis, in which the bladder walls are free from invasion by tubercle bacilli. I have recently had enough experience with biweekly and weekly instillations of bichlorid of mercury in strengths of 1-10,000 to 1-5,000 to believe this drug has a place in the local treatment of tuberculosis of the bladder, but outside of this I know of no treatment except complete excision of the diseased area.

In excising tuberculous areas in the bladder both mucosa and muscle should be included, and if there is a suspicion that some of the disease remains, or if it is necessary to open into the peritoneum, a vesicovaginal fistula should be made. This places the bladder at physiologic rest as long as may be deemed necessary. It makes the bladder suture safe, and prevents infection and pressure ulcers that may occur with a retention catheter in the urethra. A small strip of iodoform gauze should lead from the bladder into the vagina for the first 48 hours to prevent the fistula from closing. The fistula may easily be closed under local cocain anesthesia when its purposes have been served. If future experience should demonstrate the desirability of removing a portion of the bladder with the ureter, this operation in multiparas and women with large vaginas will probably be performed through the vagina. After freeing the ureter down to the uterine vessels, a finger beneath the end of the ureter makes a safe guide for puncture through the vaginal wall with sharp scissors. The ureter is dragged down through this puncture opening, and the vaginal wound is enlarged according to the area of bladder to be resected. After resection of the diseased area the deeper portion of the bladder and vaginal wounds may be closed, leaving the portion nearest the internal urethral orifice open for the purposes of a vesicovaginal fistula. The ureterectomy was finished through the vaginal route in Cases II, III, XXII, and XXV. In Case XXII, I removed a considerable area of thickened muscle of the bladder wall with the ureter, and opened into the bladder mucosa.

Treatment of the Ureter.—While, as stated above, the ideal operation in case of thickened ureter is nephro-

ureterectomy, we are not justified in adding the ureter operation unless the patient is in fair condition. We have not yet had enough experience to say just how much or how little harm may come from leaving a diseased ureter *in situ*. Case XXIII suffered for some months after her kidney was removed, from intermittent abscess formation in the pelvic portion of her ureter. After days of fever, malaise, and pain, the accumulation of pus would discharge into the bladder, and the patient would experience instant relief. A priori one would suppose that the presence of a diseased ureter would influence the bladder disease. And it probably does at first, but we know that physiologic rest for the ureter is followed in many cases by quiescence of the tuberculous process and atrophy of the organ. Of the 4 cases known to have a bladder lesion at present, two still carry the diseased ureter and have a lumbar fistula. Of the 11 cases with bladder symptoms only three have the ureter.

An analysis of our cases throws some light upon the problem of wound healing. Of the 9 nephrectomy cases, one, Case XXI, died. Case VI is reported in good health but nothing is said as to wound healing. Case XIII was closed at operation and healed by primary union. Cases XV and XVIII healed before they left the hospital. Case XVII is still open after 3½ years, the rib probably being infected. Case XXXIII is open after 17 months, and Case XXVIII is open after 14 months, a piece of gauze having been discharged from her wound after 5 months.

Of special interest are the cases of nephrectomy and partial ureterectomy, because of the opportunity to examine the ureter microscopically. Of the 7 specimens, 2 were not examined, 4 were tuberculous, and 1 showed a chronic ureteritis. Of the cases showing a tuberculous ureteritis, Case XIX healed at once before leaving the sanatorium, Cases VIII and XXIII closed after 2 years, and Case XXIV is still open after almost 2 years. Case IX, with chronic ureteritis healed in 4 weeks.

From the 13 cases of nephroureterectomy, 9 ureters were tuberculous, and 4 showed chronic ureteritis. In the 4 cases showing chronic ureteritis the wounds closed promptly in Cases I and XXVI, while in Case XII there was granulation for 6 months and in Case II for 5 years. The 9 tuberculous ureter cases closed soon except Case XXV whose lumbar wound is still granulating after 14 months. The tardy healing in Cases II and XII can be explained only on the supposition of wound infection from the kidney during the operation. Of the 3 cases of nephroureterocystectomy, Cases XVI and XXXII died and the wounds in Case XXXI healed promptly.

Of the 23 cases in which the whole or a part of the ureter was removed the ureter was examined microscopically in 22, and of these 17 were tuberculous while 5 showed chronic inflammation. From the above analysis it appears first, that tuberculosis of the ureter exists in a large proportion of cases of tuberculosis of the kidney; second, that a wound may close rapidly after the partial removal of a tuberculous ureter or it may suppurate for years after the complete removal of a non-tuberculous ureter; but that as a rule, the partial removal or the leaving of a tuberculous ureter is followed by months or years of suppuration, while the complete removal results in rapid closure of the wounds.

After-treatment.—In all cases of abdominal operation it has been Dr. Kelly's practice for a number of years to give the patient a liter of salt solution before she leaves the operating table. This is given either as a high enema, a subcutaneous infusion, or it is left in the peritoneal cavity. This allays thirst to a great extent and flushes the kidneys, the patient passing about the normal quantity of urine in the first 24 hours. In all kidney operations this operation infusion is supplemented by enemas of salt solution given every 4 to 6 hours for the first day or two. These enemas are small, containing from 200 cc. to 600 cc. of fluid, to which nour-

ishment may be added. The enema should be of body temperature or slightly warmer, and it should be given slowly, preferably by means of a rectal tube and gravity funnel.

In case oliguria or uremic symptoms develop after operation, the amount of fluids should be pushed and the patient treated much as one would treat acute Bright's disease. The skin and bowels should be kept active. The patient may be kept in blankets. Heart depressants must be avoided after a severe operation. Diuretics are indicated and are preferably given with the enemas. The infusion of digitalis is one of the most useful. I have had most gratifying results with the diuretic pill composed of squill, digitalis and calomel, 1 gr. of each. This pill acts well on both the bowels and kidneys.

Summary of Results.—One patient (Case XIV) has not been heard from since leaving the hospital.

Five patients (Cases IV, V, XVI, XXI, XXXII), or 14%, have died; two (Cases XVI and XXXII) from the results of the operation. Cases IV, V, XXI and XXXII had involvement of the other side, the first 3 dying from this cause.

Two patients now living, after respectively 8 and 14 years (Cases II and III), may have tuberculous infection of the remaining kidney.

Eleven patients (Cases III, IX, X, XII, XXIII, XXIV, XXV, XXVII, XXVIII, XXXIII, XXXIV) still have bladder symptoms or are known to have a bladder lesion. The elapsed time since operation in these cases has been 14 years, 1 case; 5 years, 2 cases; 4 years, 1 case; 2 years, 2 cases; from 18 months to 6 months, 5 cases. All but one of these patients are in good general health, five of them reporting better health than they have known for many years.

Case XVIII still has partial incontinence of urine due to treatment of the urethra before she was admitted to the sanatorium. She has no trouble after 3 years due to the tuberculosis.

Two patients (Cases XXIX and XXX) on dismissal 6 months ago had colon bacillus infection of the remaining kidney, but they had very little pus in the urine, no symptoms, and considered themselves well. Case XXIX was seen December 8. She had gained 30 pounds in weight, the bladder was normal, but the colon bacillus infection was still present in the remaining kidney.

Ten patients (Cases I, VI, VIII, XIII, XIX, XX, XXII, XXVI, XXXI, XXXV) are reported or known to be in perfect health. The elapsed time since operation has been 8 years, 1 case; 6 years, 2 cases; 5 years, 1 case; 3 years, 2 cases; 2 years, 2 cases; 1 year, 1 case; 6 months, 1 case.

Case VII was operated on for pelvic and abdominal tuberculosis in June, 1902, 6 years after her kidney operation. A letter to Dr. Kelly in December, 1903, from California, reports fair health, and the pursuit of field work in botany.

This gives us 25 out of the 35 cases, or 70% to be classified as having either fairly good or excellent health.

Cases XI and XV are in poor health (each after 5 years) with evidence of chronic interstitial nephritis.

Cases XVII and XXXIII have lung tuberculosis, but Case XVII is doing heavy work as a maid and Case XXXIII (already mentioned as having cystitis) is in apparent good health.

General Summary.—Tuberculosis of the urinary system is a surgical disease, being, as a rule, unilateral, and often the only focus of tuberculosis in the body.

If the disease is bilateral and there are no pronounced symptoms referable to the kidneys, the treatment should be that usually accorded tuberculosis of the lungs, viz., suitable climate, nutritious diet, and proper regulation of the patient's rest and exercise; but if one or both sides begin to cause marked local or general manifestations, surgical intervention is often of great benefit.

In case of bilateral disease, or in associated disease of

the lung, the anesthetic is of great importance. Local cocaine anesthesia may be used for nephrotomy, and nitrous oxid gas for nephrotomy, nephrectomy, or nephroureterectomy.

Thickened ureters are generally tuberculous; and should be removed with the kidney if the patient's condition justifies.

Bladder disease in these cases is often nontuberculous, and removal of the diseased area should not be attempted at the first operation. If the bladder fails to heal within a year under ordinary methods of cystitis treatment, the disease is probably tuberculous, and if not occupying more than half of the bladder, it should be excised.

PERVIGILUM, OR LONG PERIODS OF PHYSIOLOGIC WAKEFULNESS.

BY

GEORGE M. GOULD, M.D.,
of Philadelphia.

Sleeplessness as a result of pathologic conditions of the brain or mind has often been described,¹ and especially the very general and extreme illustrations in the insane are well known. There are other instances arising from shock, etc., which show at least the influence of morbid action, as, for instance, the case cited by Winslow² of a woman who was horrified at finding her husband dead at her side in bed. There are also cases of "idiopathic sleeplessness," in which weeks may pass without 5 minutes of continuous sleep, and in which the intellect does not show disorder, and there are no symptoms of bodily and mental fatigue, etc. Winslow cites the case of Paganini, who, he says, rarely slept, "so intense was his passion for music." Boerhaave is recorded not to have slept for a period of 6 weeks in consequence of his brain being overwrought by intense thought on a profound subject of study.

In this connection may be quoted a passage from the *Semi-Monthly Medical News*, of 1859:

The question how long a person can exist without sleep is one oftener asked than answered, and the difficulties of answering the question by experiment would seem to leave it forever unsolved. A Chinese merchant had been convicted of murdering his wife, and was sentenced to die by being deprived of sleep. This painful mode of death was carried into execution under the following circumstances: The condemned was placed in prison under the care of three of the police guard, who relieved each other every alternate hour, and who prevented the prisoner falling asleep, night or day. He thus lived 19 days without enjoying any sleep. At the commencement of the eighth day his sufferings were so intense that he implored the authorities to grant him the blessed opportunity of being strangled, guillotined, burned to death, drowned, garroted, shot, quartered, blown up with gunpowder, or put to death in any conceivable way which their humanity or ferocity could invent. This will give a slight idea of the horrors of death from want of sleep.

But all such cases are plainly different from those in which a healthy person in obedience to duty or affection does not allow himself to sleep for an extended period of time. In the issue of *American Medicine* of February 6, 1904, there is mention of a physician who slept only in his sleigh while being driven from patient to patient, for a period of as much as two weeks. But, of course, such sleep, with good health, can satisfy the demands of the organism.

Dr. Charles Mackay³ says:

¹ I formerly attended a patient who rarely closed her eyes in sleep for 10 consecutive minutes for nearly a year. Her existence under these circumstances was perfectly miraculous.—FORBES WINSLOW.

² Obscure Diseases of the Brain and Mind.

³ The Scenery and Poetry of the English Lakes.

Wordsworth in speaking of Southey said, "He fell a victim, not to literary toil, but to his strong affection for his first wife, which led him night after night, when his labors of the day were ended, to watch with sleepless anxiety over her sick-bed." The strongest mind, as he observed, will ultimately give way under the long-continued deprivation of the natural refreshment of the body. No brain can remain in permanent health that has been overtaken by nightly vigils, still more than by daily labor. When such vigils are accompanied by the perpetually recurring pain of beholding the sufferings of a beloved object, and the as perpetually recurring fear of losing it, they become doubly and trebly injurious; and the labor that must be done becomes no longer the joy and solace that it used to be. It is transformed from a pleasure into a pain, from a friend into an enemy, from a companion into a fearful monster crying, like the daughter of the horse-leech, "give! give!" It is then that the fine and delicate machinery of the mind is deranged. It is then that the "sweet bells are jangled and out of tune," that the light is extinguished and the glory under a cloud, that Eternity may lift but not time. Such it appears was the case with the amiable Southey; the grand, if not the great poet, the accomplished scholar and the estimable man in every relation of life.

Forbes Winslow in discussing the "Pathology of Sleep,"¹ says that "a state of pervigilium, or watching, cannot with impunity be extended beyond 18 or 20 hours, except in the mindless, thoughtless state of mania."

Probably physicians, more frequently than any other class of men, choose or feel compelled to endure prolonged sleeplessness. Three or four cases have come to my notice, the details of which may be of interest to us both as physiologists and as brother physicians. They are particularly trustworthy and of value physiologically because the reports are made by most honorable physicians trained to observe and report accurately such phenomena.²

The case of Dr. W. L. Rodman, of Philadelphia. Dr. Rodman writes:

In April, 1890, my youngest child was born; 3 weeks afterward my wife was taken desperately ill, with what proved to be a most malignant attack of scarlet fever, contracted from my eldest daughter who had such a mild attack that she never went to bed and never had throat symptoms. The diagnosis was made too late to protect her mother from infection. In her weakened condition my wife—always susceptible to throat troubles—became desperately ill from the onset. She was attended by a laryngologist and two excellent general practitioners. She refused to have a trained nurse and would permit no one save myself to nurse her. As far as I can say I slept not at all for eight days and nights. I am very sure that I never laid down or had off my clothing during this time. Of course it is possible that I may have slept in a chair but very unlikely, as I never could do that, and had I fallen asleep under such circumstances, would have, in all probability, slept long enough for me to be conscious of it.

I kept myself awake by drinking black coffee freely. At the end of eight days when my wife had sufficiently improved for me to be willing to rest I found sleep impossible. I was compelled for the only time in my life to take a hypnotic.

In 1881, when a surgeon in the U. S. Army and stationed at Fort Linn, I. T., I was compelled to go five days and nights without sleep. My colleague had diphtheria and he felt that tracheotomy might be necessary any moment and I was the only medical man within 100 miles of the post. I did the routine work of the post during the day and sat up each night with my friend, Dr. Williams, until relief was sent from another post. I believe that the length of time one can go without sleep depends entirely upon circumstances. Some can doubtless go longer than others; all can go longer than they perhaps think if affection, duty, or both require it.

The case of Dr. T. B. Greenley, of Meadow Lawn, Ky., according to his letter to me of January 7, 1904, is as follows, using his own words. This is his sixtieth year of active practice. He is now 86 years old.

"... of my long campaign in 1846 of going 18 days and nights continuously without lying down to rest in that time. It was in September of that year, the disease being malarial in character. I practised in the valley below the city of Louisville, and had to visit patients in five counties and two States. I went on horseback keeping three horses. I could take near cuts by paths through woods or fields and get to patients quicker than in a buggy, and of nights more safely. As to sleep, all I got was on the horse. When going toward home I knew the horse would keep the right road and I could brace myself in the stirrups and go to sleep in two minutes. If the horse stopped or anyone

looking for me spoke to me I was awake immediately. I was always awake at the bedside, examining patients or putting up medicine. The disease being malarial, and curable, I only lost one patient between July and Christmas, although I had 12 cases of pernicious, or congestive intermittent fever. I did not think I could, or anyone else could go so long without rest, but there was so much sickness I hated to give up and went as long as I could. On the eighteenth day at night I got home about ten o'clock and told my wife I was bound to rest, but it was no use to try to sleep at home as it was Hello! all the time, so I would hide till morning. I went to the stable loft and made my bed on the hay, when I got a good rest, as well as sleep. In those days I did not mind a week's campaign without rest or much sleep, but of course I could not do the same now, although I feel as well as I ever did. I am not to say very old yet, only being in my eighty-sixth year.

The Case of Dr. R. Matas, of New Orleans:

The facts (says Dr. Matas in a personal letter) are simply that for 15 days and nights I did not sleep. I worked at my practice during the day, and at night I demonstrated practical anatomy from 7 to 10 p. m.; I then sat up writing and reading by the side of a patient who interested me very much. I kept awake by shower baths, coffee, and tea, and at the end of 15 days my patient rallied and improved; then when I might have slept, I could not; I found no rest, no comfort in bed, and in spite of my best efforts I kept awake and suffered from insomnia for weeks, until finally I got into equilibrium again, but not until I had paid the penalty in an outbreak of uric acid manifestations, which have left their impress upon me to this day. I broke out in a general eczema and pruritus, which I was not able to relieve until I took thyroid extract; then I suffered from intercostal myalgia and other evidences of muscular rheumatism accompanied by excessive uratic excretion. All this finally passed, but still I suffer occasionally from muscular pains which remind me forcibly of my old indiscretion. To this day I drink Vichy (Celestins) 50 liters per month, and pay the French government indirectly an annual contribution of \$120, which has been going on for eleven years, in solemn remembrance of that unfortunate experience.

Dr. Matas adds:

It is not an unusual doctor's story. But the lesson to be gathered is that every man has his own way of making a fool of himself, and that we doctors often obtain this distinction by sacrificing ourselves to our patients and throwing away to them the better part of our lives, heedless of the time when our sacrifices avail us naught, except to serve as a warning to our less sentimental and more sensible successors.

The Case of Dr. Buffington, of Baton Rouge, La.—Dr. Matas, of New Orleans, writes as follows:

The case of Dr. Buffington, who died a few months ago in Baton Rouge, is another. He died in his ninth decade, and practised medicine over 60 years in the same county. He had an enormous obstetric practice, and during the more active years of his life it is well known that for weeks and months he would never go to bed, but would sleep as best he could in his buggy while driving from one patient to another.

FAMILY PERIODIC PARALYSIS.¹

BY

GEORGE E. HOLTZAPPLE, M.D.,
of York, Pa.

Much has been written lately on the subject of periodic paralysis, yet it remains a disease which is unique in its manifestations, obscure in its pathology, and of rare occurrence. I desire in this paper to give a brief history of this affection, as I have seen it in a family extending now along some branches, through a period of four generations. My observations have been made during the last 20 years. The characteristic symptoms and clinical phenomena of the cases heretofore reported, by European and American observers, are similar to those which characterize these cases. In the cases thus far reported, I have failed to learn of any deaths due to this disease, and, on the contrary, I believe the disease is not considered serious. Of the family of which I write, a number have died in an attack, and many have suffered from periodic sick-headache, which I always regarded as equivalent to an attack of paralysis, both having a common cause, whatsoever that may be.

A typical attack of this peculiar paralysis is charac-

¹ Journ. Psycholog. Med., Vol. v.

² The names of the physicians are given at my particular request in order to insure that credibility and authority which is desirable.

¹ Read at the meeting of the Medical Society of the State of Pennsylvania, held at York, September 22, 23, 24, 1903.

terized by periodic flaccid motor paralysis involving all the voluntary muscles, except those of the face, eyes, tongue, organs of speech, of deglutition, and of the sphincters of the rectum and bladder. The paralysis may be partial or complete, general or localized. The upper extremities alone, or only the lower may be involved. It may be confined to the neck, or half of the body may be completely paralyzed, while partial paralysis affects the other half. The attack may be partial in the morning and become complete during the day.

When one of these patients suffers from complete general paralysis he is utterly helpless, cannot move a finger or toe, neither lift nor turn the head on the pillow, and, if unsupported, it either drops on the sternum or backward between the scapulas. In some instances breathing becomes distinctly labored, and deep breathing, cough and vomiting are impossible. The bowels almost never move and urine is seldom voided during an attack, unless the bladder is over-distended. There are absolutely no psychic symptoms. The mind remains perfectly clear, and in a patient who died in my presence it was clear until the last moment. The onset is almost always at night, and is ushered in during sleep, with either very slight or no premonitory symptoms. The patient may retire with a feeling of weakness in the extremities, which usually comes on toward evening, or he may have a voracious appetite, which, if appeased by indulging in rich food, is sure to precipitate an attack. On waking he may find himself helpless, able to speak and swallow, but unable to move head, extremities, or trunk. In some cases speech, deglutition, and breathing, may be affected.

None of the special senses has been involved in these cases. There are no sensory symptoms, save in some instances formication and numbness in the paralyzed parts, also a sense of heaviness and a tired feeling, which at times becomes very annoying to the patient, and of which he is greatly relieved by frequent change of position. Patients during an attack usually have no desire for food, some suffer slight nausea, but they usually take nothing but water, until they have fully recovered. In an ordinary attack the circulation remains good; the color of the lips and fingernails is normal and capillary circulation is not sluggish. During a very severe attack I have seen the pulse weak and irregular, with evidence of cardiac dilation. Some patients during an attack are almost constantly affected by congestion of the conjunctivas and the mucous membranes of the respiratory tract. The accumulation of mucus in these cases may, at times, greatly embarrass breathing. During an attack of complete paralysis, the reflexes and the faradic excitability are abolished in the paralyzed part, but return with the restoration of motor power. Most of these patients during an attack complain of absolutely nothing except that they are helpless. The duration of these attacks may be a few hours, or one, two, and, in rare instances, three full days. Improvement may be abrupt and of very short duration, or it may require three or four hours, or even a half day. Vomiting and one or two loose movements of the bowels sometimes occur during the period of improvement. Some of these patients contend that forced exertion aids materially in hastening improvement or in warding off an impending attack. The first symptom of improvement is simply the ability to produce slight muscular contraction here or there, maybe in a finger or toe, soon followed by ability to move a large portion of the part involved. Some will complain the day following of an attack of muscular soreness, especially if they had to be handled much. Others do not complain of anything following an attack.

It is nothing uncommon for one of these patients to be as helpless as a log at 7 a.m. and at 11 a.m. be engaged in doing a hard day's work, not feeling the slightest inconvenience from having been completely paralyzed a few hours before. In some, improvement is more rapid

when it begins in the upper extremities, and in others when it begins in the lower.

Some can predict for a certainty an impending attack, others can not. A heavy meal, especially in the evening, is sure to precipitate an attack in some, while others are not affected by the quality, or quantity of the food taken.

The number of this family who have had attacks of paralysis is 16. Eighteen have been affected with sick-headache. Five have had attacks of paralysis and headache. Eleven members have had attacks of paralysis alone, and 13 have had attacks of only headache. The total number affected with either attacks of paralysis or of headache or both is 30.

This disease was transmitted through the father having had attacks of paralysis, in six instances, through the mother in three instances; through the father having had attacks of sick-headache, in four instances, through the mother having had attacks of sick-headache, in seven instances. In nine instances the paralysis was transmitted through the father, and in seven instances through the mother. Six of the number reported, died in an attack, one death occurring in my presence. In five of these cases the disease was transmitted through one of the parents having had only sick-headache; and in one instance the father had attacks of paralysis, and finally died in an attack. The parents of the first generation who suffered from this disease were F. O. and M. O., of German descent. Both parents were hearty and well, except Mr. O., who was afflicted with periodic sick-headache. There is no neuropathic history obtainable. The first generation consisted of five males and five females. Three of the sons had attacks of paralysis, one had attacks of headache, and one was unaffected. Of the daughters four had sick-headache, none had attacks of paralysis, and one was unaffected. I will append a number of histories, some very brief, others more full.

CASE I.—Mr. M. O., a member of the first generation, now aged 68 years. His early personal history is negative. He never used alcoholic stimulants, but used tobacco rather freely since he was 15. There is no luetic history in the whole family. His boyhood days were spent in a store until he was 15, when he began an apprenticeship as a bricklayer. He suffered from his first attack of paralysis at 14. His attacks always came on during the night. To indulge in a rich meal, especially in the evening, was sure to precipitate an attack during the following night. A heavy cold would also predispose to an attack. There were no premonitory symptoms. He would retire feeling well, to wake up and find himself helpless. In a severe attack he would be unable to move a finger or toe, neither could he take a deep breath, and speech was often difficult. He could usually swallow well, and the muscles of the eyes and face were not involved, while the muscles of the neck were often completely paralyzed.

He never suffered from headache, and there were no mental symptoms. His appetite was usually gone, nausea was common, but he was never able to vomit. His bowels never moved during an attack, and he always had full control of the sphincters of the rectum and bladder. He never had pain in the extremities, even if handled by the nurse. The paralyzed parts often felt numb.

Present Condition.—On examination I find he is well nourished, and his color is good. His body is full of warts; he has nevi of the face, the color of the mucous membrane is good, his tongue is slightly coated, and there is slight arcus senilis, although the arteries at the wrist are not stiff.

Pulse is 80, regular, full, and strong; cardiac impulse rather weak, apex beat in the fifth interspace within mammillary line. The heart sounds are clear, and aortic second sound is not accentuated. Respirations 20, breath sounds clear; there is no cough unless he feels an attack when there is an accumulation of mucus and a desire to cough. Cough is common when the paralysis is partial, otherwise not possible. The muscles of the extremities are slightly emaciated, and those of the lower ones so weak that locomotion is impossible. The extensor muscles of the extremities are all slightly stronger than the flexors. Tactile and painful sensations are normal above the hips. The weakness in the lower extremities commenced 16 years ago, and increased gradually until two years ago, when he was compelled to take to an invalid chair; his arms, though weak, are strong enough to work the wheeled chair. The special senses are unaffected, and there are no mental symptoms. The pupillary reflexes are normal. The tendon-reflexes of the upper extremities are scarcely to be elicited, and those of the lower extremities are abolished. The sphincters of the rectum and bladder are not affected.

CASE II.—Dr. C. F. O., son of M. O., had one attack when 24. He has a son and daughter, thus far unaffected.

CASE III.—Mrs. J. G., daughter of M. O., now 30, has had repeated attacks since she was 15. The characteristic symptoms of her attacks are similar to those of the attacks in her father. She never had headaches.

CASE IV.—Mr. L. G., aged 16, a son of Mrs. J. G., had a number of typical attacks of periodic paralysis.

CASE V.—Mr. J. O., a member of the first generation, began to have attacks of periodic paralysis at 20. He never had headache, and except for the attacks of paralysis had very little to complain of. The attacks were of frequent occurrence until he reached the age of 54, when he died in an attack.

CASE VI.—Mr. J. O. Jr., began to have attacks of paralysis at 16. The attacks were often of weekly occurrence, most severe during the damp and cold months. At the age of about 25 he went to Missouri, had an attack, and died.

CASE VII.—Mrs. L. P., daughter of J. O., had attacks of headache until she was 31, when the headache ceased, and she began to have periodic attacks of paralysis. The following note of a recent attack serves to portray the peculiar behavior of this malady:

On April 13, 1903, she retired feeling well. At 1 a.m. she awoke, and found she was unable to turn, upper and lower extremities were paralyzed, except that she could move hands and feet. At 5 a.m. improvement commenced, and at 9 a.m. she had recovered completely. She then cleaned a few rooms in her house, and retired at 10 p.m. feeling perfectly well. At 4.30 the following morning she awoke and was again almost helpless. On forced exertion she improved for the time being, managed to remain up, until 12 o'clock noon, when she became worse, and at 3 p.m. was completely paralyzed. I saw her at 6 p.m.; she could move her head from side to side, but could not lift it from the pillow, neither could she move a finger or a toe. She suffered no pain when at rest, but a rather severe, dull, muscular soreness when handled. There was some numbness in the extremities. There were no mental symptoms, and the special senses were not affected. Speech and swallowing were unaffected. Pupils reacted to light and shade very readily. Color of lips and mucous membranes was good, and capillary circulation was active. Temperature was normal, respirations 20, pulse 80, full, regular, of good volume, no diastolic tension normal. Her appetite was good, but she was afraid to eat. There was no nausea. She drank water freely and without difficulty. The bowels had not moved, and urine was not voided since she was completely paralyzed, yet she felt that she had complete control of the sphincters of the rectum and bladder. Breathing was sometimes a little labored and deep breathing impossible. Heart-sounds were clear, cardiac impulse easily felt, and apex beat in the fifth interspace within mammillary line. Tactile and painful sensation normal. The tendon-reflexes and the faradic excitability of the muscles involved were lost.

April 16 I called to see her at 10.30 a.m., and found her absent from home, she having called on a neighbor. She returned and reported feeling perfectly well, save for a little muscular soreness, which she attributed to being handled. Her appetite was good, pulse 76, respirations 20. The tendon-reflexes and faradic excitability were fully as marked as in health.

At 6.45 the preceding evening, as was her custom in such a condition, she took 2 gm. (30 gr.) of potassium bromid and .065 gm. (1 gr.) of caffeine citrate. At 7.30 she felt decided improvement. At 8 p.m. she took another dose of the same medicine. Improvement continued and was complete at midnight. She declares that improvement is never as rapid in her case when she sits in a chair as when she lies in bed.

CASE VIII.—C. O., a member of the first generation, began to have attacks of periodic paralysis which recurred at intervals during a period of three years, when he died in an attack.

CASE IX.—Mrs. J. G., a sister of C. O., never had an attack of paralysis, but had, on an average, one attack of sick-headache a week during her whole lifetime, each attack lasting about 24 hours. She seemed to be benefited by vomiting but not by sleep. She was a moderate eater, though rich meals, at times, did not seem to predispose to an attack. During an attack she was often chilly and nervous, but had no visionary disturbances. She never had convulsive seizures.

Thirst was always an indication that improvement would set in. The only other disease that she ever had was pneumonia. During the last three years of life she became very weak and uncertain in her gait. At times she was almost helpless in her lower extremities, and sensation was much diminished. The upper extremities were apparently unaffected. She died at 76. Mrs. J. G. had seven children, three sons and four daughters. All of the sons suffered from headaches and the paralytic attacks, and all of them died in an attack of paralysis.

CASE X.—Mr. F. G., son of Mrs. J. G., began to have attacks of periodic paralysis at 17. His early history is negative, except that he had spasms when quite small. His attacks of paralysis recurred at intervals of a week, or three or four months, most frequent in spring. The duration varied from a few hours to three full days. The attacks came on during the night, and lack of exercise predisposed to a seizure. He had the headache more frequently than the paralysis, and an attack of headache was certain to protect him for a while from an attack of paralysis. He never suffered any pain during an attack, nor muscular soreness afterward. He was actually a

big eater, and the paralytic seizures were always preceded by a voracious appetite that was difficult to control, yet satiety by indulging in rich food was sure to precipitate an attack. He had no premonitions except the bulimia. During an attack of paralysis his appetite was gone, bowels remained quiet, and he retained control of the sphincters of the rectum and bladder. He was usually troubled by an accumulation of mucus in the bronchial tubes, which at times embarrassed his breathing. His mind was always unaffected.

His last attack came on during a Saturday night, and continued until the following Monday, when I was called at 9 a.m. to relieve him of the accumulation of mucus, which had embarrassed his breathing very greatly. I found him cyanosed, breathing very much labored, pulse very irregular, and at times not perceptible at the wrist, with physical signs of cardiac dilation. His mind was perfectly clear. I was with him until 9.30 a.m., when his pulse suddenly ceased to beat at the wrist, there was a vacant stare, and he was dead. His age was 27.

CASE XI.—Rev. E. O. G., a brother of the preceding patient, would sometimes have a tired and drowsy feeling toward evening that would betoken an impending attack of paralysis. Sometimes an attack was preceded by slight jaundice. The onset was always at night. His attacks began at 16, and recurred at intervals of a few days to a few months, being most frequent during damp, cold months. During an attack he would suffer from a lame, tired feeling, which would necessitate frequent change of position. Improvement was sometimes abrupt, at other times it would require a few hours. He was often completely paralyzed in the morning, and in a few hours would be engaged in doing a hard day's work, not suffering any inconvenience from having been completely paralyzed just shortly before. His appetite and general health were usually very good immediately after the return of motor power. His last attack came on during a Saturday night and continued until the following Monday at 4 a.m. There was nothing unusual in the manifestations or behavior of this attack until at the hour mentioned he told his wife, who was nursing him, that he felt very badly, and expressed a wish to be turned on his side, which was done, when he requested to be quickly turned to his former position, and he was dead.

CASE XII.—Mr. F. G., another brother of the preceding patient, had colic for one week, when he was taken with periodic paralysis one evening and died the following evening, aged 43.

CASE XIII.—Mrs. J. F., a sister of the preceding brothers, gets attacks of headache and mild attacks of paralysis.

CASE XIV.—Mrs. G. H., a daughter of Rev. E. O. G., is a frequent sufferer from periodic paralysis. Her age is 22. She gives positively no premonitory symptoms. Overeating, exertion, excitement, or worry does not seem to predispose to an attack. Attacks are more frequent in damp weather, and to lie in a draft at night is sure to precipitate an attack. When paralyzed she is simply helpless, and has no pain anywhere. She may suffer from some sore throat, and from an accumulation of mucus in the bronchial tubes. The paralysis may be partial or local, and appetite remains good. There is no nausea, nor vomiting during the height of an attack, nor during the period of improvement, which was not uncommon in the case of her father. She does not seem to be affected by the kind or quantity of food taken.

The following note was made March 3, 1903, at 10 a.m.: She retired the evening before at 11.30 feeling well except for being slightly tired. During the night she awoke and was paralyzed. On examination the patient complained of little pain and soreness throughout the body. There were no sensory symptoms, no numbness, tingling, nor formication. There was no muscular twitching. Muscles of the neck and extremities were paralyzed; tactile and painful sensations normal; reflexes and faradic excitability in the affected parts abolished. Pulse regular, full; tension normal. Cardiac impulse strong, apex beat within nipple line, cardiac sounds clear, no murmurs. Respirations 21, not labored, but she was unable to take a deep breath; capillary circulation active. Temperature, normal. Pupils reacted to light and shade very readily. She has little headache; eyes not sensitive to light. She had full control of sphincters. Urinalysis and microscopic examination of urine were negative. Leukocytes 8,800; otherwise nothing abnormal was noted in the examination of the blood.

CASE XV.—H. F., of the second generation, the son of Mrs. J. F., is one of the worst subjects of this disease now living. He gives no specific nor alcoholic history; had most of the diseases common to childhood. He began to suffer from sick-headache at 9. Had frequent attacks which were most common during damp seasons. At 16 he ceased to have headache, and began to have attacks of paralysis. The attacks in this case are usually preceded by a tired, dull, irritable, sleepy feeling. There is usually some twitching of the muscles of the neck, trunk, and extremities, beside a dry, stuffy feeling in the head; also a slight cough, injected conjunctiva, and a numb feeling which gradually extends over the entire body. If he retires with these symptoms he is almost sure to wake up and find himself paralyzed. If the paralysis is incomplete, the flexors are more affected than the extensors. The muscles of the face are, at times, partially paralyzed; swallowing and speech may be affected, and breathing is often labored, which is aggravated by an accumulation of mucus. Any gastric disorder is apt to be followed by an attack of paralysis. He has had involuntary

movements of the bowels as well as incontinence of urine during an attack.

The following note was made January 25, 1903, at 10 p.m.: He felt the onset of an attack and was scarcely able to walk. He complained of a dull, stuffy feeling in the head, slight cough, and a general numb feeling. He also felt impelled to move all the time. His color was good, no cyanosis, no jaundice; had a few rales in the chest; vasomotor reflex marked; pupillary reflex active and knee-jerk slightly increased. The flexor muscles were weaker than the extensors. The temperature was normal, pulse 70, respirations 22. He took sodium bromid 2 gm. ($\frac{1}{2}$ dr.) and caffein citrate .065 gm. (1 gr.). This dose was repeated in one and a half hours; he retired and a few hours later awoke and found himself all right.

The following morning at 8.30 his temperature was 98°, pulse 70, respirations 22.

He had slight headache and general muscular soreness and tenderness, which was a common sequence in his case.

He has two brothers and one sister. One brother and the sister got headache after the age of 9. The brother ceased to have headache at 16, then had a few attacks of paralysis—none since. The sister ceased to have headache at 20, and afterward had frequent attacks of paralysis.

Pathology.—We are still ignorant of the pathology of this disease. A necropsy would doubtless reveal much that would explain the pathology of this disease, but none was thus far obtainable in this family. No other deaths have yet been reported to my knowledge. Theories have been advanced but none has yet been proved by demonstration. Some observers believe this condition is due to a toxemia affecting the nerve-endings of the motor fibers in the muscles. Goldflam also discovered vacuolation of some of the muscle fibers.

Personally I always regarded this condition as a vasomotor neurosis, affecting the blood-supply to the anterior horns which are almost wholly supplied by the anterior spinal artery.

I do not know that vasomotor nerves have ever been demonstrated in the vessel walls of the spinal cord, but vasomotor centers do exist in the anterior horns, and it is not likely that the arteries supplying so important a tissue as is found in the anterior horns would not be supplied with vasomotor nerve regulating influence. The nutritional changes noted in the muscle fibers may be due to disturbance of function of the trophic cells. The exciting cause, be it toxic, may have a direct influence on the vasomotor nerves regulating the blood-supply to this part of the central nervous system, or it may have an indirect influence, when due to gastrointestinal disturbance, or when paralysis results from sleeping in a draft.

The progressive permanent paralysis, which occurred late in life in two of the cases here reported, I always thought was likely due to a slow progressive degeneration in the anterior horns, due to frequent disturbance of nutrition and the atrophy of the muscles due to involvement of the trophic cells. Only a careful necropsy will determine the validity of this line of argument.

The paralysis in this disease always appeared to me as closely allied to the paralysis which sometimes occurs in migraine or hemicrania, such as oculomotor paralysis, aphonia, and paralysis of one extremity or of half of the body.

Treatment.—Believing that the attacks of hemicrania and paralysis in this family have a common cause, and on the assumption that both conditions are a vasomotor neurosis, I resolved to try large doses of bromid with caffein. I began this treatment 18 years ago, immediately after witnessing a death reported in this paper. The dose of bromid usually consisted of 2 gm. ($\frac{1}{2}$ dr.) potassium bromid with .065 gm. or .130 gm. (1 gr. or 2 gr.) caffein citrate; and this dose was repeated, if necessary in one or two hours.

This seemed to give unmistakable relief, so that from this time on most of those who were subject to this disease kept the medicine on hand, and, without exception, these patients were certain that while it did not cure, it did have a very decidedly abortive influence, and hastened improvement, when taken during a paroxysm.

Prior to this nothing was attempted but prophylactic

measures when exciting causes were known. Prophylaxis is an important matter with some, for if, in the presence of severe acute catarrhal inflammation of the respiratory apparatus, one should be so imprudent as to indulge in heavy food, life might soon be in danger.

In this respect this report differs from all others I have read. In one case reported, Rev. E. O. G. took one or two doses during the evening if he felt an impending attack and for a period of two years he did not fail to meet a pulpit appointment. He was then taken with a febrile affection which he attributed to the medicine taken, and from this time he took no more bromid. During the two years he took the medicine, he felt the attacks often. After his febrile attack he was free from the disease for about a year. He was then taken with an attack on a Saturday evening, which continued until Monday at 4 a.m., when he died very suddenly. This was the first attack after he had discontinued the bromid. He did not take the bromid unless he felt an impending attack, which he was always able to do.

A number of these patients have told me that they feel an improvement invariably, a half-hour after taking the medicine. I do not know of a single instance in which a severe attack developed when the bromid had been taken during the onset.

Small doses of bromids have been used by other observers with apparently no benefit, but I never prescribed small doses, only large ones with a view of making a decided impression on the nervous system. The frequency of the attacks does not seem to be affected at all by the use of the bromids.

Those suffering from hemicrania seldom take anything for fear their headache may cease and they become subject to attacks of paralysis, for in a number of the cases reported it has plainly been shown that these attacks are but the equivalent of an attack of paralysis.

SOME PULMONARY LESIONS PRODUCED BY THE BACILLUS OF HEMORRHAGIC SEPTICEMIA OF CARABAOS.

BY

PAUL G. WOOLLEY, M.D.,

of Manila, P. I.

Pathologist, Government Biologic Laboratory.

The lesions caused by the bacillus of hemorrhagic septicemia in cattle are legion. Subcutaneous and lymphatic suppurations, gastrointestinal ulcerations, and hemorrhages, widespread subcutaneous and subserous edemas, pathologic joint conditions, and varying types of pulmonary changes are frequently seen, sometimes alone, but usually accompanied by ecchymoses.

During the epidemic of hemorrhagic septicemia through which the government carabaos have lately passed, we have had opportunities to study many of these lesions.

Among the animals dead of the prevailing infection was one in whose lungs were lesions so like those of contagious peripneumonia that we were at some loss to make a positive diagnosis until careful pathologic and bacteriologic examinations had been made. Unfortunately, the autopsy had to be done under such unfavorable circumstances, and so hurriedly that there are necessarily some gaps in the protocol that cannot be filled, yet the known clinical facts, together with the bacteriologic and pathologic findings leave no room for doubt as to the nature of the disorder.

CASE I.—Pleuropneumonia. The animal was a fairly well-nourished carabao that had arrived at Manila (from Shanghai) 3 days prior to coming under our observation. It had seemed well and had acted in a perfectly normal manner since landing. On the evening before death the overseer had noticed nothing peculiar about it. There was no cough, and it ate and drank. The next morning the animal was found dead in its stall.

Since its arrival in Manila it had been with the rest of the

herd that had come from China at the same time, and while a few of these died, it was proved that they had died of hemorrhagic septicemia, and they had showed no lesions similar to those found in this animal. Since its death other members of the herd have died also, but in these there have been no lesions resembling pleuropneumonia.

The autopsy was done early in the afternoon of the day of death. On opening the body there was none of the subcutaneous gelatinous edema that has been so characteristic in the cases of hemorrhagic septicemia which we have studied. Neither were there any extravasations of blood in the subcutaneous tissues.

The abdominal cavity showed nothing remarkable, though the liver presented a number of abscesses in which flukes were found.

The remarkable lesions were in the thoracic cavity. When this was opened, a quantity of pale, clear amber fluid gushed out. In the residual liquid in the pleural cavities were some fibrinous shreds. The pleural surfaces were, for the most part, covered with a wellmarked fibrinous exudate, which could readily be peeled off, leaving a reddened, congested, roughened surface. The pleura itself was thickened and edematous. The subpleural tissues were in places filled with a serogelatinous exudate, and this condition was most marked under the mediastinal surfaces. The mediastinal connective tissues were completely filled with the same gelatinous material. The pericardium in its whole extent was lined with a fibrinous exudate, and its surfaces were separated by a serous fluid containing flakes of fibrin.

The lungs were not collapsed, and contained air only in the anterior and apical portions. Cut surfaces of the organs were firm and red, in some places very dark, and divided by fine and coarse bands of what looked like edematous connective tissue, so that the whole section had a marbled appearance. These bands varied from $\frac{1}{8}$ inch to $\frac{1}{2}$ inch in thickness and were in places quite saturated with serum, and even honey-combed with small cystic areas filled with a bluish-looking, gelatinous material. There were no hemorrhages in the thoracic organs, except in the heart. The right auricle of this organ was nearly black with large and small confluent hemorrhages. The mediastinal and preapical glands were enlarged, pale, and showed areas of necrosis.

Bacteriologic Examination.—Smears made from the heart's blood, from the liver, lungs, and preapical lymph-glands, showed a considerable number of small, oval, polar-staining bacilli. Cultures were made on agar, from the heart's blood, and from the bands in the lungs. Within 24 hours small, translucent, shining, moist colonies appeared on the surfaces looking like dewdrops. The organisms comprising these colonies were short rods, which when stained with $\frac{1}{2}$ carbol fuchsin or carbol thionin, showed well-marked polar staining. All the cultures made at autopsy gave the same kind of growth, and the organism was present in pure culture. The other features of this bacillus were that it did not stain by Gram's method, did not form spores, did not liquefy gelatin, and did not coagulate milk. In peptone solution, after 24 to 48 hours' growth at 37° C., it gave a well-marked cholera-red reaction.

Intrapleural injection of small amounts of broth culture (25 cc., 48 hours' culture) killed a guinea-pig in something less than 20 hours, and a postmortem examination of the dead animal revealed a well-marked fibrinous pleuritis, a fibrinous pericarditis, and hemorrhages into the pericardium and pleura. The lungs were partially solidified. The pancreas was surrounded by a gelatinous tissue which produced the impression that the organ had been embedded in a perfectly clear gelatin. The organism was recovered in pure culture from the heart's blood and pleural exudate, and smears from the heart, liver, kidneys, spleen, and lungs showed apparently the same organism.

Pathologic Examination.—In sections from the lungs the air spaces contained a granular material, and an occasional leukocyte or desquamated endothelial cell. The bloodvessels were all intensely congested, and filled with red blood cells. The mucous membrane of the bronchi was desquamated in some places, and these tubes contained a fibrinopurulent material. The bands seen at autopsy were, for the most part, composed of fibrin and leukocytes, but the largest of them, those extending down from the pleura, also contained a considerable amount of fibrous tissue. The smaller bands ran in all directions across the lung tissue. Such bands were rather sharply outlined from the surrounding edematous lung tissue, but they contained the hyaline, degenerating remains of the air cells which they had involved, and which were filled with leukocytes. It was in these fibrinopurulent bands that the bacteria might be seen in sections stained with methylene blue and eosin, and it was from one such band that the cultures described, were obtained. Occasionally about such bands a wellmarked leukocytic infiltration was observed, so that the tissue appeared like that in the gray stage of hepatization in pneumonia; in such cases the bacilli were present in the air spaces. These bands were not homogeneous. Some were comprised of nearly solid masses of leukocytes and fibrin, but many of them were formed of an external layer of polymorphous cells, leaving an intermediate clear space, free of cells, but across which fine filaments of fibrin were interlaced. Occasionally, too, other larger cells of endothelial origin were enmeshed in this fibrinous lace-work. Then, too, the conges-

tion, which was general, was more intense about these bands. There were no signs of periarterial fibrosis, but on the contrary, the bloodvessels seemed normal save for the congestion.

The liver shows no more than wellmarked congestion of the centers of the lobules.

It seems that this may be considered a pure case of infectious pleuropneumonia, and not one of the contagious type.

The facts in the clinical history seem to support Theobald Smith's theory of the etiology of the disease. The ocean trip, a rough passage, rough handling, all would tend to produce the primary bronchopneumonia and emphysema, upon which the later states follow. In this case, the bronchopneumonia was perhaps the first stage of the disease. The presence of a very infectious disease in the same herd would account for the presence of the causative organism in the lungs of the infected animal. But even without the bacilli of hemorrhagic septicemia in other animals, the organisms might have invaded the weakened animal from the upper respiratory tract, where they might have been present, and probably were, if the same conditions hold here as in the cattle that Moore examined. There is, too, a very good reason for the presence of these organisms in cattle here, if, as has been proved in other places, they are present in water. The health of the carabao, or water buffalo, depends to a great extent upon the daily bath, which is usually taken in a wallow, in the thick mud of which the animals immerse or embed themselves until only the ears, eyes, nose, and horns are visible. Frequently the whole head disappears from sight. Habits of this sort offer every inducement for such organisms as are present to enter the animal. However, we have not been able to demonstrate the bacillus of hemorrhagic septicemia in the water or soil.

CASE II.—The animal was very weak when first observed, but in fair physical condition otherwise. The conjunctivas were somewhat congested, respiration was rapid, and the feces normal. Temperature 40.2° C. When taken off the truck at the laboratory it staggered a few steps and fell on its side. There were numerous bruises on the body, probably the result of a rough voyage across the China Sea. It ate food when placed near it and also drank, although it did not apparently suffer from thirst. It had no cough. During the next few days it became a little brighter and somewhat stronger. On June 6 it was again weak and could not stand up, the hind legs seeming to be especially feeble. It gradually became weaker and diarrhea developed, but with no traces of blood or mucus. Death occurred on the ninth day after landing.

The postmortem examination showed a few patches of subcutaneous edema on the sides. There were a few small pericardial hemorrhages about the base of the heart. The lungs showed a number of subpleural nodules, which on section exposed granular areas, similar to those seen in bronchopneumonia, in the stages of red and gray hepatization and suppuration. The suppurating areas were filled with a thick, granular, greenish-yellow, sticky material.

Cultures were made from the lung abscesses on agar and blood-serum. After 24 hours at 37° C., the agar tubes showed a growth of small transparent grayish, round colonies. The blood-serum showed a very scanty growth of small colonies. Transfers were made from these tubes to various other media, and plates were also made. After a careful study of its morphologic and cultural characteristics, it appeared that the organism under consideration was a short bacillus with round ends, and nonmotile. Its measurements varied between 1.0 micron and 2.0 microns in length, and 0.3 micron and 0.5 micron in thickness. The largest forms were seen in glucose media, the smallest on potato. From the animal blood it showed well-marked polar staining, although this was not so distinct in organisms grown on artificial media. It was stained easily with the usual watery anilin stains, but was not stained by Gram's or Weigert's methods. The rods, as a rule, occurred singly, often in pairs, occasionally in chains of 5 or 6 individuals. The appearance of the growths on the usual culture media was in no way characteristic. The colonies on agar were small, grayish, transparent, and well circumscribed, with little or no tendency to spread. On all the solid media approximately the same appearance was noticed. In gelatin, liquefaction was caused. In bouillon, a granular deposit was formed on the sides and bottom of the tube. During the first few hours of growth the whole medium was faintly clouded, but as the sediment was deposited, the liquid became clear. After a few days the sediment became viscid, as could be shown by shaking the tube, when the precipitate rose, not in floccules, but in threads. In Dunham's peptone solution the same general characteristics were observed as in broth, but the growth was not so abundant.

The cholera-red reaction was produced by the addition of sulfuric acid (free from nitrites) at the end of 24 to 36 hours. No phenol was detectable. No gas was produced in solid glucose or lactose media, and the reaction of the media was not changed. Milk was unaffected, even after 2 weeks. No acid was produced, no coagulation occurred, and there was no reduction of the litmus. Stab cultures in solid media showed nothing remarkable; the growth followed the line of inoculation closely, with no tendency to spread, and extended to the bottom of the punctures as a finely granular growth composed of small colonies. The surface growth was small, just surrounding the point of entrance of the needle.

This organism was pathogenic for monkeys, small birds, rabbits and guinea-pigs, when injected subcutaneously, intravenously, intrapleurally or intraperitoneally. Death was the result of a septicemia or acute seropurulent inflammation with subsequent septicemia.

Sections of the lungs in this case showed a general edematous condition with wellmarked congestion. There were some areas of emphysema. The peribronchial tissue was infiltrated with red blood cells and leukocytes, which filled the air spaces and which were enmeshed in a network of fibrin. Occasional bands of fibroid tissue were met extending down from the pleura. Some of these showed infiltration with leukocytes. There was no perivascular fibrosis.

The pleura itself was thickened but showed no evidence of chronic inflammation. The tissue beneath it was, however, infiltrated with small round cells and showed wellmarked new vascular formation.

CASE III.—A native horse. In this case no clinical history was obtained. The lung lesions corresponded with those in Case II. There was likewise a gelatinous edema about the base of the heart. Cultures were made from the small abscesses and nodules, and in smears and cultures an organism was present that agreed in every detail with the ones from Cases I and II.

The sections from the lungs showed congestion. The air cells were either widely distended, or filled with a fibrinopurulent material or a granular material that resembled coagulated albumin. As a whole, the fibrous tissue in the lungs was increased. There was a considerable subpleural accumulation of well-formed granulation tissue, and there was an increase of peribronchial fibrous tissue. The bronchi were filled with fibrinopurulent material in some cases mixed with the desquamated lining cells of those tubes. In some places, too, the lining mucous membrane of the bronchi was thickened. Extending down from the pleura into the pulmonary tissue were some considerable bands of fibrous tissue, but in this case they showed but little round-celled infiltration and no leukocytes.

The smaller consolidated areas resembled the gray stage of hepatization. The larger ones were veritable abscesses in the sides of which the hyaline remains of air spaces could be seen, but in the center no such remnants and only the nuclear material and cells undergoing karyorrhexis.

These cases then were examples of the invasion of the lungs by the bacillus of hemorrhagic septicemia. How they gained access to the lungs we cannot state with absolute certainty, but we suspect that they came from the upper air passages and that the pulmonary invasion was subsequent to a bronchitis in all 3 cases. It is tolerably certain too that in all of the cases, death was the result of a terminal septicemia incident to the entrance into the blood stream of the organisms which were present in the lesions of the lungs.

TEMPORARY SUTURES FOR HEMOSTASIS.

BY

WILLIAM C. WOOD, M.D.,

of Gloversville, N. Y.

Gynecologist to Nathan Littauer Hospital, Gloversville, N. Y.

The control of arterial hemorrhage may be easy for the hospital surgeon surrounded by trained assistants and supplied with a multitude of special instruments, but to the general practitioner, miles away from home perhaps, and armed only with his pocket case, with only the assistance that frightened and excited friends can render, it is a serious thing. Even if professional assistance can be had, it is usually confined to one medical man, who must give his whole attention to the perhaps unfamiliar matter of giving ether.

An easy, practical, sure method of controlling bleeding suggested itself to me a few years ago, and it has proved so satisfactory in so many cases that I wish to present it to the profession. It may be that it is not original with me, yet I have never seen mention made

of it in the textbooks, nor has it ever been spoken of to me by any surgeon I have met.

It consists of the application of a temporary deep suture passing under the artery, either in the wound itself or above it; this suture may be of catgut and be left till absorbed, or of silkwormgut or silver wire, or in a great emergency, of strong linen thread; in the latter cases it may be removed as soon as the danger from bleeding is over or the artery is tied in a more regular way. Thus, with little more danger of sepsis than would result from giving a hypodermic injection, bleeding can be controlled and the doctor have time to proceed with preparations for an aseptic operation if one is necessary.

The following case reports will illustrate the practical application of this method:

CASE I.—A girl, aged about 24, was walking on the railroad track when she was run over by a switching engine; the wheels passed over her left arm, crushing it nearly to the shoulder. Some time after, she was found lying on the track and was taken to the Nathan Littauer Hospital. It was, of course, necessary to amputate the arm at the shoulder-joint.

The patient was anesthetized, the arm scrubbed carefully, and an incision made through the deltoid, making the external flap, the humerus was disarticulated and the knife then carried down close to the bone as far as desired to make the inner flap. Before cutting this off, however, a long curved needle, threaded with coarse catgut, was passed down deep into the tissue of the flap and tied tightly in a bow-knot. The flap was then cut off and the arteries tied at leisure, the provisional suture untied and removed, and the flaps brought together with sutures. The amount of blood lost was surprisingly small, and the patient made a prompt recovery.

CASE II.—I was called one night by Dr. McCulloch of Gloversville, N. Y., to see a man who was bleeding arterially from an ulcer on the forehead, which had been treated with an arsenic paste. Pressure had failed to stop the blood, and artery forceps would not hold. Two deep sutures of catgut were placed just outside of the border of the ulcer in the healthy skin, which stopped the bleeding; the sutures were left till absorbed.

CASE III.—A young man while cutting bands on a threshing machine received a deep stab wound in the biceps muscle, severing an artery. His fellow workmen corded the arm but not enough to control the hemorrhage and when he arrived at my office, coming from four miles out in the country, he had lost about all the blood he could well spare; I bared the arm, gave it a hasty scrub with hot water and green soap and then with a long curved needle threaded with silkwormgut took a deep stitch in the muscle about an inch above the wound, applied an antiseptic dressing and sent him home with orders to return the third day. He came back the next day complaining bitterly of the pain caused by the suture, which I made a pretense of loosening, advising him at the same time to bear it a little longer, which he did till the fourth day, when I removed it.

If this method had not been pursued in this case, a very much collapsed patient would have had to wait until I could have secured assistance; he would have had to take an anesthetic; he would have had a large wound instead of a small one; and he would have been disabled a much longer time.

CASE IV.—A physician who was miles away, phoned to me about midnight stating that he had a case of secondary hemorrhage in a patient whose hand had been frightfully burned from grasping a live wire, and that he could not get his artery clamps to take hold nor could he control it by pressure. I suggested that he use the deep suture, which he did, controlling the bleeding till morning when he was able to cut down upon the artery and tie it in what seemed to him to be the more scientific manner. He did not remove the provisional suture until the other was secure.

The foregoing instances are enough to show how generally useful and how successful this method of controlling bleeding is and it is therefore not necessary to multiply reports of cases. It is an emergency method and used as such will not only add to the comfort and give relief to both patient and doctor but its promptness will save lives, which is of much greater consequence than more finished or brilliant operative procedure.

The American Federation of Reciprocating Examining and Licensing Medical Boards will hold a meeting at the Great Northern Hotel, Chicago, Tuesday, May 24, 1904. A cordial invitation is extended to the various state boards to send delegates of representation.

A PLEA FOR THE MEATUS.¹

BY

A. NELKEN, M.D.,

of New Orleans, La.,

Consultant, Clinic Genitourinary and Venereal Diseases, Touro Infirmary.

In a recent paper² I used the expression: "A cut meatus and all the woes which that entails." Since the publication of this paper I have been asked several times to explain why the results of a cut meatus should be referred to as woeful.

Both in hospital and private practice I have frequently seen men upon whom a meatotomy has been done. Not a small number of times I have performed this trivial operation myself. A little cocaine, a cut with knife or scissors, and we have an urethral opening through which we can work without difficulty. Among medical men the opinion seems to be general that meatotomy is inconsequential and can be done without hesitancy whenever it seems to be indicated. On looking up the available literature on the subject, I find but one writer who disapproved of the operation. Most authorities do not hesitate to recommend it whenever a narrow meatus interferes with instrumental examination or treatment of the urethra. Lydston states that meatotomy is almost invariably beneficial in cases of genitourinary irritation, whether stricture exists or not.

Great stress is always laid upon a narrow meatus as a cause of persistent urethral discharge following gonococcal infection.

The advice is always given that in operating, the opening should be made somewhat larger than ultimately desired, as the tendency in healing is toward contraction. This recommendation is frequently followed so well that I have seen meatuses which would admit readily a 36 Fr. sound. Sometimes the result of the operation is actually an artificial hypospadias.

I do not mean to be placed on record as believing that meatotomy is never justifiable. An abnormally small meatus (under 18) may require division for the treatment of pathologic conditions in the urethra or bladder.

Stricture of the meatus (due usually to balanitis or ulcer) is a pathologic narrowing in which surgical interference may be justifiable. But I believe that the responsibility of a moderately contracted meatus in the gonorrhea is frequently exaggerated and, certainly, we should eliminate other possible factors before the meatus. In the last two years—that is, that the organ has begun to question the expediency of the operation. I have done but one meatotomy, and during blood and pleurae failed to recognize the necessity of this kidneys, spleen, were of chronic urethritis.

Pathologic Examination. Contracted meatus I mean one which air spaces contained a gr and 22 Fr.

leukocyte or desquamated element on 1,000 measurements, were all intensely congested. The mucous membrane of the meatus to be 24 of the some places, and these tubes to find an adult whose urethral material. The bands seen at aut measurement will often composed of fibrin and leukocytes to be capable of considerable amount of fibrous tissue. meatus will admit a 20 all directions across the lung tissue. use occasion for cutting sharply outlined from the surrounding or treatment of the but they contained the hyaline, degenerated cells which they had involved, and leukocytes. It was in these fibrinopure, the acorn tipped bacteria might be seen in sections stained with eosin, and it was from one such described, were obtained. Occasional wellmarked leukocytic infiltration went there is always tissue appeared like that in the gray picture of large calipneumonia; in such cases the bacilli spaces. These bands were not homoprised of nearly solid masses of leukocytes chiefly responsible of them were formed of an external treatment of gonocells, leaving an intermediate clear light of our present across which fine filaments of fibrin sionally, too, other larger cells of al Society. enmeshed in this fibrinous lace-work hea, New Orleans Medical

knowledge of the subject, is the absurd statement that gleet is *always* dependent on urethral stricture, Otis himself has, in his urethrometer, devised an instrument which, properly used, would save many a meatus from division in order to facilitate the passage of sounds for the cure of stricture which exists only in the surgeon's fancy. The Otis urethrometer is too well known to require description. Closed and with rubber cover it will readily pass an 18 meatus.

It should be introduced as far back as the bulbomembranous junction and then opened until the patient feels the distention of the canal. According to Otis this occurs as a rule when the dial records a dilation of 32. Later authorities consider 30 as the average. However it is well not to be too arbitrary in fixing a limit. I have seen men of ordinary development who complained of no discomfort with a dilation of 40 Fr. to 45 Fr.

On slowly withdrawing the instrument while dilated, the exact position and caliber of any stricture can be defined. Otis, who was a faddist on urethral stricture, said that, as the urethrometer has no shoulder to catch on withdrawing as has the bulbous sound, we might overlook stricture of large caliber. It may be laid down as a fairly safe rule that any stricture which permits the urethrometer, dilated to 30 Fr., to pass unnoticed, is a stricture of very questionable importance.

The urethroscope is essential in the precise treatment of chronic urethritis. While the larger caliber tubes necessarily give the more exact results, still I have done very satisfactory work with as small a tube as No. 20, using direct light. The shorter the tube, other things being equal, the better the view, and the penis can be so crowded down over a fairly short tube, as to bring the entire anterior canal under observation.

Nor does the presence of stricture necessitate the sacrifice of the normal urethral orifice. It is not my intention to discuss this condition, save in reference to meatotomy. In cutting operations there can rarely be a good reason for dividing the normal meatus. When we desire to employ gradual dilation, the ordinary metal sound can be used up to the caliber of the meatus. Beyond this point dilation can be continued with the urethral dilator. The Oberländer, covered, will pass through an 18 meatus, and in my hands has given very satisfactory results in the treatment of urethral stricture. Superior to the Oberländer are the Kollmann and Powell dilators. They will pass a 22 opening.

When the meatus will admit of their employment, these latter instruments, especially the Powell, which opens evenly and not cone-shaped, as does the Kollmann, give entire satisfaction. Dilators have the advantage of being easily introduced, are painless, and permit more gradual dilation than do sounds; although with them, pressure is not so uniform. So much for the diagnosis and treatment of pathologic urethral conditions without division of the normal meatus.

If, however, no undesirable results followed this trivial surgical procedure, we might reason that its convenience is sufficient excuse for its performance. Let us consider whether this is the case.

One can hardly question that the fan-shaped spraying stream of the man whose meatus has been cut is disagreeable to its possessor. Patients have repeatedly told me that sexual intercourse is not as pleasurable after the operation as it was before.

But these objections, while of weight, do not compare in importance with the fact that a small meatus is a protection against urethral infection. The apparent immunity of some men, in spite of a very lax sexual life, may, I believe, often be explained on this ground. My attention was early attracted to the fact that men upon whom a meatotomy had been done were prone to develop a urethritis after almost every impure sexual indulgence—not a true gonorrhea, as a rule, but a simple urethritis, due to contact with a septic or irritating discharge in the female acting on a canal whose normal

resistance had been already weakened by disease or by excessive instrumentation.

I have been able to find but one writer to agree with the foregoing conclusions. In Park's "Surgery," Belfield says: "Division of the meatus should never be performed if that orifice admits a 22 Fr. bulb; for while the operation is trivial, the result is a gaping deformity of the natural nozzle-shaped orifice, whereby the expulsion of urine is unfavorably influenced and the patient's liability to gonorrhea and urethral chancre undoubtedly increased."

This forceful opinion succinctly expresses the objection to the operation. So convinced am I that its results are malicious that I think a plastic operation frequently justifiable to restore the normal caliber of a meatus disabled by free meatotomy.

SPECIAL ARTICLES

MEDICINE AN EXACT SCIENCE: QUERY.

BY

JOSEPH CLEMENTS, M.D.,

of Nutley, N. J.

Member of the American Association for the Advancement of Science.

It is confessed by savants that there is but one little bit of absolute knowledge—the to-and-fro motion of ether waves, alike in every part of the universe—the results of the achievements of the past. Knowledge is largely relative.

In an editorial of the *Journal of the American Medical Association*, August 10, 1903, the writer says: "If one critically examines the number of points positively established in medical science he may be surprised to find how few they really are. Every other branch of science is in the same condition, more or less, according to its age and nature." Marked progress, however, obtains in all departments of science.

Take astronomy, for example. The sun 50 years ago was estimated to be 95,000,000 miles distant from the earth. Today it is less than 94,000,000, and our planet is considerably less than the 8,000 miles in diameter as measured at that period. Now, while advance in science has secured this greater exactness, the basic principles—the central body, the motion of the planets, their orbits, the solidification phenomena—all these were points established long ago, and progress had been along the lines of exactness in interpretation and adjustment of these.

It is so in almost all departments of science. In medicine, however, fewer of the basic essential principles may be said to be established. This is so because it cannot be claimed that any consensus of view and doctrine prevails in regard to the principle, alike fundamental in medicine as a science, and operative in organic phenomena. The physics and chemistry are points settled mainly as to their role in the phenomena, but the "something else not identified with any known physical and chemic activities" (Simmons), which is not distinctly recognized and allowed for, seems to be a point not positively established.

Leaving out biology and medicine, or, more specifically, biology in its relation to medicine, and the great family of sciences may be said to be established in regard to their general basic principles, and progress in exactness of interpretation and utilization of these to all practical ends, is the watchword of the future.

However, it remains for medicine to establish its foundation principle, to bring it into distinct recognition, to interpret its facts, and thereby step to its place and evidence its entity as among the foremost and the most exact of the sciences.

The question of the hour is in regard to the force operative in living things, unique to protoplasm, and specific to organic processes. Specifically the nature of the potentiality, or the terms by which it is designated is not a matter for concern and adjustment here and now, but the fact that life phenomena, organic processes, cannot be accounted for on a hypothesis of chemistry and physics, or effected potentially by their sole

energy must be recognized and confessed, or disproved. This is the bar to medical progress.

The anomalous conditions in medicine are, that while acknowledging—for who does not?—that protoplasmic activities embrace the whole dynamics of organic phenomena, yet hypotheses are advanced and acted upon ignoring the magisterial role of protoplasmic potencies, and hypothesizing other potencies—pathogenic properties in so-called germs of disease, and active principles in drugs; the one active in origination of, and effective in the activities constituting pathologic conditions and processes; the other therapeutically operative in "cure." These I antagonize as untenable and unscientific.

As stated, these hypotheses are simply postulated and acted upon, and are not defended when challenged, being well nigh disclaimed when confronted.

As a result of these conditions and theories, pathology and therapeutics are unsatisfactory and unreliable. Different schools and systems of medicine obtain. Bacteriology is in much, work in the twilight; disagreement in diagnoses of pathologic conditions and therapeutics, advised in cases toward which all eyes are turned, and on the part of men equally able and eminent, are not infrequent, engendering scepticism in the people, who run to quacks—it is said there are 100,000 of them in Germany alone—and within the profession, so that there is almost a stampede to "mechanical therapeutics," which at least affords spectacular means of drawing the renegade patronage, and so relief from the burdensome conditions is secured. Nor is this an exaggerated picture, or the painting of it a pleasurable task, save that these are facts in the case.

The position assumed and maintained is, that these ought and need not be the conditions prevailing; that in its potencies and possibilities medicine is and may become actually an exact science, thus commanding the confidence and esteem of all men; as a science ranking among the most exact, as a profession commanding universal trust. The task of evidencing and maintaining this position is before us.

Did not Descartes, who classed all knowledge into three sciences, make medicine one of the three? In *Science*, April 10, 1903, there is a chart, ingeniously arranged by Professor J. McKeen Cattell, "showing the relation of the sciences." A moment's glance will make evident that a physician, while having some knowledge of the dozen sciences thus grouped, must have a pretty thorough mastery of more than half of these. Medicine includes two-thirds rather than one.

The basic principle in medicine is the fundamental principle in all biology, and its great question is the problem of the ages: What is life? Medicine need not blush that it, perhaps, more than any other science, has "points not positively established." The most momentous, the profoundest question of interest to the human mind, is the problem of life, with what it includes.

It is within the province of human intellectuality that there be an essay, dignified and in keeping with the importance and profundity of the matter, to solve this problem.

To "play with life" (Jacques Loeb), to isolate a process in organic phenomena and to excite its spectacular performance for a few hours beyond the usual after-death, and then jump to the confidence of indefinitely prolonging human life; to supply electrically a catalytic stimulus which seems to bring about parthenogenesis—where there is no need of it—and at once to conclude that "electricity and life are one and the same thing," are too puerile to associate with science in any way. Make the endeavor in keeping with the dignity of science, the publication of which will not incur the charge of "the vulgarization of science," (*Independent*, New York) and the regal nature of the phenomenon manipulated.

Meanwhile, until the "Great Biologic Problem" is solved, the point may be positively established, and a consensus of recognition obtained, that there is a force operative in living things; that protoplasmic activities are regal and dominant in organic processes.

That this fact of a special force in living phenomena is of scientific demonstration one need not fear to assert. In all vital motion it is demonstrable that the initiative is in and by the living matter, the bioplasm of the cells. Respiration, oxidation—biologic—depends entirely, in its initiative and operation

upon the protoplasm, and the activity of the cell respiration is operated and dominated by the activity of the cell protoplasm—cell respiration and protoplasmic activities are identical.

The union of gases with liberation of energy is oxidation in inorganic chemistry. In biologic or physiologic chemistry the phenomena are more complex, and the dynamics are more complex, too. Oxidation in the lungs is by union of gases there, CO_2 being given up and oxygen taken into the cells and passed on into the cellular and other tissues. This is by force of protoplasmic activity, driven by its energy.

The theory of force stored in food-stuffs is only evidenced and the force liberated and transferred in the presence of protoplasmic activity; the anabolism of physiologic digestive phenomena is not in evidence in the artificial, which is simply chemic. It is surely impossible not to recognize a force special to and operative in a magisterial sense in living processes, though it seems to put one under the ban to speak of vitality under the present pressure of the trend of scientific thought—a fact marvelous in view of the facts. The recognition of the sovereignty and unity of protoplasmic activities in which the property and force unique to protoplasm is on exhibition, competent and efficient to organic phenomena of every grade and class, is the key to exactness in medical science, and failure in this recognition is the secret and cause of the anomalies to which reference has been made. Thus in study and research in organic phenomena the conviction is forced upon one that these have their specific force, alike in all their grades, call it what you will. Other forces are in evidence—chemic, electric, etc.—cooperative and adjuvant, and always under the sovereignty of the life energy.

Dr. Huxley's physical basis of life, protoplasm, is thus the depository of the life force; here it may be said to be "resident," and in a sense in which such language may not be used in regard to any other cosmic matter of which we have knowledge. Whether the hypothesis that every particle of matter is endowed with a force or energy specific to itself be true or not, we are driven by the facts in organic phenomena, to the conviction that germ plasma holds a psychovitalistic force as an endowment, and in no such sense is a force predicable of any other known substance.

However this may be, medical facts interpreted in recognition of protoplasmic activity as the operative agency in organic processes will rid medical science of its confessed anomalies, and place it in the front rank with those that are approaching exactness.

In the exactitude which this would give the vague and ill-defined notions of disease now current would be impossible. What is disease? May it have been evolved from a germ? We have a "germ theory of disease." What can it mean? To name a disease and to add a drug as its "cure" is present day commercial medicine, on the theory that "for every disease there is a drug that will cure it."¹ Out of such notions has arisen the commercialism of a bottled and marketed pharmaceutical cure for the ills of the flesh, with the many millions of revenue to patent medicine makers and venders. This is a really serious and vital question in medicine, demanding some sort of interference. Disease is a process, a phenomenon. It is a congeries of organic processes, protoplasmic in origin and nature and effective operation; processes that are graded, progressive, and in a sense classic and unique; for instance, syphilis, pneumonia, tuberculosis, etc. These phenomena have causes and initiatory conditions, but are effected by the energy operative in all organic processes. Pathologic processes are abnormal physiologic processes.

Exact medical science will recognize more distinctly than appears to be general, that causes in disease are not the active agencies in the processes, and will specifically distinguish between that which has, in the causal sense, given rise to, or provoked the phenomena, and the processes themselves. These are protoplasmic activities; they are neither bacterial nor chemic, save in a sense causal or provocative and adjuvant to the protoplasmic, which are solely regal. So that to cause disease and to originate the phenomena, scientifically speaking, have a world of difference between them, and it is vital that the distinction be distinguished.

¹ In a popular medical journal.

Causes in pathologic phenomena may be inert, active, or chemic, the two latter may not be synonymous. A microorganism, as a cause in disease, is active in its own physiologic functions, a microbe, even, must eat to live. In the generation of gases and liberation and transformation of energy in these microorganic vital functions, we have, additional to the contact presence of the microbic body, the active chemistry of these functions. Also in the effect of miasmatic inhalations, and in defective or abnormal phosphoric oxidation—largely causal in tuberculosis—we have initiation of chemic operations. In these, with the atomic and molecular changes accruing, we have a large account to place to the credit of the chemic side of this summary of causal determination in disease.

Causes in pathologic conditions may have a further relation to the processes to which they have given rise, and a closer relation, in becoming cooperative and adjuvant, rendering more complex as well as more violent, the abnormal processes in operation. Is it not an error to suppose that causes in disease are always active, that the splint or bullet always carries in microorganisms which are active in the pus formation and inflammation which follow? Sterilize the cinder particle and drop it in the eye and the same disturbance will result as from a bit of cinder from the smokestack of the engine. A microorganism, its life functions, its only properties and activities (bacteria do not make vinegar as bees may be said to make honey), may be causal in disease, its life activities, with chemistry involved, being concomitant and also adjuvant to the pathologic processes which its irritative presence may have occasioned. Just so a drug, mineral or vegetable, inert in itself, may become active in chemic processes which arise on its combination with other matters within the vital domain, the inert thus becoming active. It is a principle in biology that vital motion is modified by every substance that has contact relation with the living matter, and it may be added that the kind and degree of the modification or change will be determined by the nature of the matters coming into juxtaposition. An inert substance, simply by its irritant contact may stimulate or modify protoplasmic activity. The role of microorganisms, active in their life functions, and that of drugs, with the augmented chemic processes accruing, reveal large possibilities in causal phenomena, and furnish the key to the etiologic interpretation, and the basis of therapeutic science.

But these causal agencies leave intact protoplasmic activities as the dominant agency and entity, equally in pathologic and physiologic processes.

I submit the question, does not this furnish a more rational and scientific interpretation of the phenomena under discussion than the impossible hypotheses of pathogenic properties possessed and actively exerted by microorganisms upon superior organisms, and of drugs, of imaginary curative properties and therapeutic potentialities?

As Virchow himself came to realize in his later years, "Disease is the response of the vital processes to the stimulus of the cause," and "Bacilli are never more than the cause in tuberculosis." I find more than that, the added adjuvant relation, direful in provocation and intensification of the pathologic and destructive phenomena. The special force operative in these processes is the active agency in embryologic evolution and organic existence, inherent to the organism, yet needing specific environment and the stimulus thus afforded. Seeds only germinate in the environment of soil, moisture, temperature, etc. Given these and the potential becomes active.

Metabolism is the primordial act of life. The presence of nutrient matter is part of the necessary stimulant environment. Given the proximity of nutrient substances to the cell protoplasm—respiration oxidation being always concomitant, and metabolism follows in exhibition of protoplasmic activities. Thus, in interpreting the facts in physiology, pathology, and therapeutics, the instrument, microscopic and mental, must be turned mainly and specifically to the superior organism where the phenomena are in progress.

It is not too much to claim that we have here the basis of exactitude in medical science, in which empiricism may largely be eliminated, and the principles may be applied specifically. In acne, Gilchrist makes the microorganism the chief point of observation and investigation. He has found these organisms

apparently to figure largely in the processes and has distinguished them by the term "*Bacillus acnes*." In this complaint we have a petite yet unique congeries of pathologic processes. Here are papule, pustule, nodule, as grades or stages, indicating processes and changes, superficial and deeper, involving mischief in the interstitial and structural tissues—a picture of graver diseases. Now, the bacilli may have causal relation to the phenomena—a point not yet positively proved. Its adjuvant and baneful role seems to be more in evidence, as seen in the contents of the products of the abnormal cell proliferation, which disfigure the surface of the parts affected. Protoplasmic activity is the agency effective in the abnormal operations. The papule or pustule is in no sense the product of the bacillus, whose utmost part played in the drama is that of irritant, provocative of the modified vital motion, of which the pustule is the product. To make the microorganism the chief study and matter of research in interpretation of the pathologic conditions does not commend itself as a scientific procedure in the case. An epidemic occurs, say dysentery. Microscopic enterprise discovers microorganisms in the dejecta. Forthwith they are isolated, classified, morphologized, tincturized, cultured, and colonized and inoculated into guineapigs and the results observed in interpretation of the disease phenomena in the human organism. Now all of this certainly has its place, more or less, in reaching a correct attitude toward the disease and its relief; nevertheless, may not such magnifying of the minor and merely causal, eclipse and obscure the importance of the major and magisterial entity in the phenomena? May not effort in this direction become too self-centered on the part of bacteriology?

The refinements of bacteriologic science warrant the statement that a single microbe, under favorable conditions, may be the progenitor of a family numbering 16,000,000, in about 12 hours.¹ No such specific knowledge of the phenomena of protoplasmic activities is attained. Why is the response of vital motion different in the use of unlike drugs? For instance, strychnin, codein, nitric acid, and others (selected at random). Nitric acid has no effect upon some inorganic substances, while in certain others it is followed by the tumbling apart of their molecules, reasons for which, chemistology makes apparent. Effects answering to these occur in regard to drugs and organic matters within an organism, and the response of the protoplasmic activities vary as the substances vary. The chemic action is diverse and so is the modification or change of vital motion in the protoplasm. Disease processes as well as therapeutic, originate in vital motion, and are the outgrowth of, or rather, are identical with protoplasmic activities. Here is the place, this is the field for investigation, a field and territory grass-grown in comparison with the beaten track of bacterial investigation and speculation, this latter being minor and of little importance save as throwing light upon the former. In the article, "Cell Implantation in the Production of Tumors,"² we have a scientific study beginning where the disease began—in the cell, the cell protoplasm. The so-called cancer germ has so far eluded all research, but it doubtless will be found. Tumor production, however, is going on in the absence of identification of any microorganism as related to it. The real agency and operative entity is in evidence here as everywhere—protoplasmic energy and activity. This is what is witnessed after inoculation of guineapigs with a virus, including microorganisms—guineapig pathologic protoplasmic activity. To interpret this as in any way the work of the bacillus, or the product of pathogenic property of the microorganism, a property and a virulence exerted by it upon the superior organism, must certainly be a fallacy.

SERUMS.

The use of serums in specific cases and conditions has a basis of reason and proved utility, and will, at least temporarily, have place in exact medical science; but with the exactitude even now attained, I do not think we are driven to the extremity of need of a "combined serum obtained from a jackass and a goat," as exploited in medical journals, in manipulation of any pathologic conditions now confronting, or in prophylaxis of such in anticipation.

Serums, in the very nature of things, and serum therapy, must have a quite limited field of operation, and a limited tenure of office, too. The position taken by Mr. Herbert Spencer, whose opinions command world-wide regard, that immunity from certain diseases obtained in the use of serums may possibly and even probably mean the loss of vital force or property which more than counterbalances the advantages of the immunity obtained, is a question worthy of serious consideration, and may at least point a conservative tale in regard to any rash use of the polypharmacy of jackass and goat serum. Most diseases are the entail of civilization. The Indian is acquiring our diseases with our up-to-date refinements. He has not yet attained to the position of cancer pathology, for to the Indian and aboriginal in general this, I believe, is at present unknown. As we approach normal conditions, or our modern modes of life adapted to them, these refinements or complexities of pathologic conditions may disappear, and the "strenuous" therapeutics of today be no longer needed. The etiology of disease is in much even yet an unexplored field. It has long been thought that we eat too much, and of improper foods, and the "nutrition experiments" now in progress at New Haven under the superintendence of Professor Chittenden, are speculatively suggestive, and may throw considerable light upon etiologic problems.

At present, however, in a limited and conservative way serum therapy may be found useful, as it certainly has proved to be in smallpox, tetanus, and other complaints. This, and the role of microorganisms in disease, and other like matters will have due consideration in the now active era of research work, and will be adjusted to their true place, or be among the eliminations necessary to the coming to exact science, which we all hail!

THERAPEUTICS.

In therapeutics, as active interference in disease processes, there is needed some reconstruction both in theory and practice.

In one of the most widely read journals appeared (April, 1903) the following: "How few physicians know the exact physiologic action of drugs, etc." To which the editor replied: "How can physicians know the exact physiologic action of drugs when there is no exact physiologic action?" The editor's reply was in the interest of exact pharmacy, of which a word later.

There is no physiologic action in drugs—the terminology is unscientific and misleading. Drugs are at least of 2 classes—mineral and vegetable. In the inorganic materia medica there are no active principles, nor is there added such property in their pharmaceutical handling. Hence the absurdity of the Hahnemannian hypothesis of "grades of potency in unlimited decennials." (Nevertheless, there is an important principle in exact therapeutics in the hypothesis, when correctly interpreted.)

In the organic materia medica, in the plant state and growing, there are "active principles," for there are classes of cells and tissues, various in their grade and properties, constituting functions, as in the animal kingdom. In the therapeutic use of animal tissues different results are obtained from thyroid, testicular, and other glands and parts of the animal, interpretable upon the fact of difference in the tissues and their atomic and molecular structure and arrangement, and the kind of chemic processes their ingestion gives rise to, and the modified or altered protoplasmic activities thus influenced or initiated. It is just so in regard to plants and different parts of the same vegetable. Some are active, while others are less so or passive in the part they play in plant physiology and embryology. But their specific activity has ceased before reaching the condition termed drugs. The only action attributable to them is the same as in the inorganic, the chemic action accruing from their combination with other elements within the organism. Some may be actually assimilable by the organism, these having nutrient relation to the organic economy, and standing in the relation of foods to the tissues. It is possible that parts of cactus grandiflora may be utilized, protoplasmically, in improving the condition of the tissues of the heart muscle in impoverishment of that viscus, especially in the earlier stages of disease arising from disturbance in the coronary arteries, interfering

¹ See address of President of the British Medical Association, at Swansea, June, 1903.

² See the Journal of the Am. Med. Asso., April 10, 1903.

with muscular nutrition. Of course, the nutrient element in drug therapeutics is not very considerable, and their dynamic role predominates.

Bring together the various elements of which drugs are composed, combining them with substances like those within the vital domain, and *inorganic chemistry* defines the laboratory processes or phenomena resulting, while in an organism they are *physiologic*, being, however, in marked particulars different, the one from the other.

The action of drugs, after ingestion, is chemic, this and nothing more. Protoplasmic activities are modified or changed in response to the irritant or other influence their material presence occasions, and the still further modified and altered influence of which the active chemic processes thus initiated are the cause.

The action following the ingestion of drugs may be first simply chemic action, this particularly of the drugs, and secondarily, protoplasmic activity—vital motion modified by the influence of the chemic action in operation. The action of drugs is simply causal and adjuvant to protoplasmic activities. Thus pathologic phenomena are protoplasmic and independent of microorganic action, save as cause, provocative of the abnormal operations in progress. So therapeutic phenomena are protoplasmic, independently of the action of drugs, which is simply chemic and causal to the physiologic processes which are en route to normal. Were drugs injected into a dead body, there might be action of the drugs—chemic action, but nothing physiologic or therapeutic. It is incorrect and misleading to conceive or speak of physiologic action of drugs, exact or otherwise. Drugs have chemic action, physiologic action is strictly and solely protoplasmic, and not to be counterfeited.

Nor is this verbal quibbling, or a matter of less than vital importance to the interests of the human race, in view of the fact of the colossal delusion of a drug "cure" for disease, saddled as a curse upon the world, growing out of this misconception.

The distinctions, as chemistry teaches, between organic and inorganic in the processes involved, are marked and characteristic. In organic chemistry we have the same tumbling apart of the molecule as in simple chemistry, but the conditions required are different, and the phenomena are dominated by a force unique to themselves, so that processes impossible to simple chemistry are in evidence in the physiologic. The phenomenon termed metabolism is impossible in simple or inorganic chemistry. Beside the pulling down and tumbling apart of molecular arrangement in organic matter, physiologic chemistry, under the sovereignty of protoplasmic activity, combines, reforms, constructs, and causes to grow, an evolution process, pure and simple, centrifugal, utterly unlike any phenomena possible to simple chemistry or obtaining in the inorganic realm. The chemistry of an organism has a specific phase, construction, unique to itself, and operated by the life force. Physiologic and therapeutic phenomena, in connection with drugs, are protoplasmic in origin and effective agency, and are the response of the vital forces to the stimulus of the drug, inclusive of the chemic action, the result of its ingestion—physiologic action is vital. The contact of certain substances with the living matter of certain cells or classes of cells is followed by a specific kind of vital motion. Empiricism has taught this; so that given precisely the same substances in the same conditions of the organism and identical phenomena will always accrue.

Again, different cell protoplasm and tissues by means of it are affected by various substances variously; in other words, unlike medicaments affect like structures differently—cellular matter responds variously to different drugs. Some drugs affect muscular structures, others the nervous, in both instances, through modification of protoplasmic activities. Certain substances, by their material contact, or chemic action, or electric phenomena, influence vital motion in direct metabolism in cell formation and proliferation, while in others the chemic action initiated by the drug is followed by liberation or transformation of energy, as seen in heightened or altered temperature, blood-pressure, etc.

These various processes are only to be thus isolated in conception and speech, in fact and in act they are, in much con-

comitant and reciprocal, change in blood-pressure, for instance, being due as much to muscular conditions of the vessel walls as to increased energy in impetus from the heart itself. So that a drug which is followed by altered pressure thus, is not merely cause of liberation of energy, but also of changes in the condition of the muscular fibers of the coats of the vessels. Protoplasmic activities are complex in a high degree.

The ultimate destiny, so to speak, of medicaments, is the bioplasm of the cells and cellular tissues. The superlatively fine matter and motion to be reached and influenced in the use of drugs, indicate the gravity of the situation, and vital importance of care in the selection of substances, and methods of preparation, and determination of form in their use to these ends. This brings me to the pharmaceutic aspect of the question in its relation to the therapeutics in exact medical science.

Exactitude in medical science is dependent largely upon exact and scientific pharmacy. The highest therapeutics can only be invariably attained in the use of invariably correct and exact medicaments. The use of quinin in the place of the whole bark marked an advance in scientific pharmacy, which was but a step to be followed by others. Thus the way was opened for the whole and exact system of alkalometry. Up to as many as 5 or 6 alkaloids have been isolated from a seed, bulb, flower, leaf, or root. Each of these is found to be of different atomic and molecular structure, with affinities and incompatibilities variant one from the other. The chemic processes to which they give rise are, of course, as variant as their chemic composition. These differing alkaloidal preparations, used empirically, have been found to be followed by varying response in the organism. The modified protoplasmic activities accruing from one or more alkaloids have been found to be subversive and detrimental to that of another in the same plant or part. In certain conditions the response following the use of one alkaloid meets the requirements in the case, the action accruing from one or more of those in the same drug in its entirety is actually lethal in those conditions, and disaster results. The danger and ill-results observed in the use of the whole half dozen, more or less, alkaloids, as found in the extracts and tincture of digitalis, is a case in point. No wonder the profession has become chary in the employment of digitalis. In specific conditions and emergencies the extract or tincture may be given for a time, usually brief, the ground gained then being held and increased by digitalin, which is perfectly safe, even in prolonged use, which cannot be said of the employment of the combined glucosids digitalin, digitalein, digitonin, digitoxin, with the coarser matters making up the leaf or seed.

Moreover, in the pharmacy of the crude plant, or part of it, how great must be the variations in its quality arising from soil and environment of rainfall, sun exposure, picking and "curing," with transit and other handlings, which no assaying and standardizing can adjust so as to give uniformity of quality and condition of the drug when it reaches the physician's office. But in the alkaloids, in their scientific preparation in the single, such assay, etc., is possible so as to secure exactness and uniformity invariably. These, therefore, must commend themselves as lending vast aid in securing exact scientific therapeutics. I certainly think that the polypharmacy of three or four to half a dozen salts in a preparation must, in view of the chemic possibilities of such a combination, create a very babel of tongues in the bell of the protoplasmic cell.

The use of the single salts of the hypophosphites, and of the alkaloids, single or combined by therapeutic skill, marks an advance toward exact medical science which is bearing good fruit. More than 30,000 American physicians have stepped to the higher ground of these advanced positions, and therapeutic scepticism will not long stand before the success they are attaining in the use of these "medicaments of precision." The consideration of this part of the subject requires a treatise of itself, but I close with a brief summary.

SUMMARY.

Diseases in their various grades—simple and complex—are a congeries of organic processes. Physiologic phenomena are such likewise; classic and of the same nature and character as to the operative force. Pathologic processes are unique and classic, having orderly and progressive grades and sequences.

Thus pathologic conditions and processes are abnormal physiologic phenomena, further to be defined as subnormal and super-normal, in endless variety of manifestation.

It is the province of medical science and the sphere of its art, to acquire knowledge of the nature and character and causes of these departures from the normal, and to manipulate and control these phenomena, guiding them back or on to normal conditions.

In doing this the various causes and conditions giving rise to or provoking and aggravating these complex phenomena, and having their part and place in the drama of disease, are to be given due consideration, and to be dealt with in modification of the erratic processes, but the burden of therapeutic interference is in the manipulation of the vital or protoplasmic processes in progress of enactment. Bacteriologic experiment and research in elucidation of the complexity of protoplasmic activities in disease may be a royal handmaid in the most difficult and most complicated undertaking ever essayed—the manipulation of the vital processes, or the handling of life. No "playing with life" in this, on the part of one knowing what he is about. The matters to be handled are "infinitely little" (Trowbridge). The phenomena are effected "in centers that are central, and yet more central" (Beale), and where only the light of thought may enter and observe, for what eye has seen that wonder expressed in disturbed protoplasmic equilibrium, with vitalization or confer and transfer of life, with its properties and potentialities in multiplex variety, its completed phenomena being metabolism and construction of the anatomic unit, the precursor or harbinger and pledge of organic evolution? To manipulate and modify these life processes, to stimulate and hasten, to check and hold in abeyance, or obliterate, to guide and turn protoplasmic forces and activities into other directions and channels, and bring, like a runaway steed, into calm and usual motion and service, is art and skill based upon science first and foremost and most exact, and a triumph second only to that which designed and originated the sublime phenomenon in its beginning.

1.—Surgical Treatment of Goiter.—C. H. Mayo reports a large number of parenchymatous goiters successfully treated in the last 15 years by combined internal and external methods, together with 110 operations for some type of thyroid tumor. Of these, 34 were exophthalmic goiter, with six deaths. He prefers the Kocher collar incision. Inspection after free exposure will indicate the best method of procedure. He uses ether unless dyspnea or exophthalmic symptoms are marked. In such cases he employs cocaine. The exophthalmic cases were all benefited within three months, about 50% became free from symptoms within three to six months. In 25% the improvement was continuous during a year, in 25% it was partial. None who lived was made worse, and those in whom death occurred were the most severe types, especially presenting tachycardia from 130 to 150. [H.M.]

2.—Local and General Anesthesia in Gynecology.—J. C. Webster uses nitrous oxid largely in pelvic examinations and this combined with ether in operations when a general anesthetic is necessary. He employs Schleich's solution, however, in many major operations, using it in plastic operations

on cervix, vagina, and vulva, in opening the abdomen, the removal of diseased tubes and ovaries, shortening of the round ligaments, myomectomy, supravaginal amputation of the uterus, appendectomy, resection of intestine, etc. A suggestive influence is sometimes added by a few drops of chloroform held over the face. He has removed a cystic fibromyoma of 87 lbs. and performed vaginal cesarean section without general anesthesia. In extreme anemia and sepsis the local method greatly diminishes risk. Division, suturing or dragging of the parietal peritoneum causes pain. Separation of adhesions between viscera or newgrowths rarely causes distress. The omentum may be ligated, divided, or cauterized without pain; dragging causes pain. Handling the intestines or appendix, or removing the latter, is not painful; pulling on the mesentery is. Compression and division of the broad ligaments is painful. Cauterization, scraping or stitching of the peritoneal surface of the uterus is rarely noticed except at the attachment of the round ligaments. Ligation, division, or stretching of these always causes distress. [H.M.]

3.—Results of Bloodless Hip Replacements.—J. Ridlon practises this operation in every suitable case, believes it is the best for all operable cases, and the only one in all bilateral congenital dislocations. That the perfect anatomic replacements are fewer than hoped should not condemn the method. He quotes Davis' description of Paci's operation with Lorenz's modifications. He divides the cases he reports into those observed by himself before his first operation, those observed from 1897 to the advent of Lorenz, those examined or operated on by Lorenz, those operated on or examined by himself since October, 1902. The statistics show about 10% perfectly stable anatomically perfect replacements, 50% to 60% of anterior transpositions or appositions and supracotyloid displacements, "good results," and about 20% to 30% of failures. He doubts if anterior or supracotyloid displacements can ever be made perfect replacements by bloodless procedure. In anterior transposition the tissues in front have been too much torn to retain the head in the acetabulum if replaced. Supracotyloid displacement is due to a deficient upper lip. When the adductors are not freely torn and the anterior tissues not overstretched, relapse into the dorsal position may occur. Then replacement may be made again and again with a reasonable prospect of success. [H.M.]

5.—Intracellular Toxin of *Bacillus Pyocyaneus*.—D. R. MacIntyre finds this toxin can be in part extracted by sulfuric acid but not by salt solution. Heat to 120° C. in the autoclave for 30 minutes only slightly diminishes the toxicity. The cell substance contains a hemolysin which may be extracted in the fresh state or after treatment with alcohol and ether by physiologic salt solution. The minimum lethal dose for guineapigs intraperitoneally is 1 to 50,000 parts body-weight. When 1 to 10,000 parts is injected subcutaneously no permanent ill-effect results. Subcutaneous injections do not give immunity to subsequent intraperitoneal injections. [H.M.]

6.—Effect of Putrefactive Bodies on Chemic Tests for Morphin.—M. W. Clift describes his experiments with Kippenberger's method of differentiation, in which he obtained crystalline residues when morphin was absent. [H.M.]

7.—A Toxin from Liver Cells.—V. C. Vaughan, J. F. Munson, and F. R. Spencer have obtained a cleavage product which when dissolved in water and injected intraperitoneally kills in the proportion of 1 part to 500. In smaller quantities there is marked emaciation with slow recovery. They have not secured marked immunity by gradually increasing the dose. After acute poisoning the liver and adrenals are congested, the spleen soft and spotted, the gastric and mesenteric vessels are dilated, with small hemorrhages under the peritoneum. [H.M.]

8.—Microscopic Observation with Lateral Illumination.—D. J. Davis uses a blackened Nernst lamp with a transparent area of 0.5 cm. at the vertex. The pencil of rays is passed through a condenser, a low-power objective answering the purpose. The essential part of the apparatus is a triangular equilateral prism so placed beneath the objective that the upper surface is horizontal, each angle being 60°. Through this, total reflection of the light occurs. A drop or two of the fluid to be examined is placed on this and a cover-slip applied. Particles

in this become visible by reflection, refraction, and diffraction. They are seen as points of light against a dark background. Particles as small as 0.005 micron are visible. This is within the limits of the size of molecules. It is a favorable method for determining motility and clumping, and probably for observing ultramicroscopic organisms, and tracing branching nerve-fibers. The writer thinks it will replace the hanging drop. [H.M.]

9.—Dangers of Potassic Chlorate.—P. Bartholow refers to the frequent errors from confounding this with KCl. Judging from the way in which it develops a toxic strength, it seems likely its molecule is endowed with an uncommon potentiality, for its pharmacodynamic effects are often irresistibly sudden and fatal. It passes unchanged through the body. Its use as a gargle has caused death. It may profoundly alter the composition of the blood suddenly and after small doses. It shows its utmost power when taken on an empty stomach. [H.M.]

1. Bilateral Facial Atrophy, with Report of a Case and Its Treatment by Subcutaneous Injection of Paraffin. BENJAMIN T. BURLEY.
2. A Many-Phased Case of Chorea. HORACE E. MARION.
3. A Case of Huntington's Chorea: Its Social Aspects. J. J. PUTNAM.
4. A New Treatment for Morphin Addiction. WILLIAM S. BIRGE.

1.—Bilateral Facial Atrophy Treated by Subcutaneous Injection of Paraffin.—Benjamin T. Burley calls attention to the extreme rarity of this condition and reports a new method of treatment. The patient is now a young woman of 23; at 8 she had a severe attack of pneumonia from which she recovered and was well until 11, when she suffered another attack, from which she appeared to make a normal recovery. It was soon noticed, however, that her face, instead of regaining its normal fulness, became progressively thinner and her cheeks were sunken. Supposing that her general system was affected she was treated by tonics, etc. The shrunken condition of the face remained though she otherwise appeared to be of normal health. After observing the patient for 2 months, it was decided to employ paraffin subcutaneously to replace the lost tissue. At the first sitting 1.5 cc. of paraffin of melting point, 109.5° F., was injected below each malar process. The subsequent swelling was slight and disappeared in 24 hours. Similar treatments were carried out at intervals of a week, the process of filling beneath the skin being extended outward and downward, both sides symmetrically. In all, nine treatments were given. The result at the end of this time is so satisfactory that no further treatment is likely to be necessary, at least for some months. [A.B.C.]

3.—Huntington's Chorea: Its Social Aspects.—J. J. Putnam reports a case in which the manifestations would not be recognized as abnormal by a casual observer. There should be a wider knowledge of the early signs in order to prevent marriage. At first the disorder seems a lack of concentration rather than true dementia, but in spite of ever increasing apathy, attacks of excitement or depression may intervene. The physician would not be justified in destroying the product of conception, even did the law permit it, as the child may develop normally, but he should advise measures for preventing conception. Increase in insanity and the neuroses is more apparent than real, and the racial stock is not injured to the extent individual deterioration would suggest. The evidence is considerable, that a child conceived during manifest insanity is not more likely to become insane than one conceived before or after this period. Persons with the disease under discussion, epileptics, and the insane should not marry, but in the milder neuroses and psychoses, when the severer ones have shown themselves only in preceding generations, more latitude may be allowed. [H.M.]

4.—A New Treatment for Morphinism.—W. S. Birge reports a treatment by which the patient is put in condition in three to five days for removal of the drug which is then completely eliminated in 72 hours without shock or discomfort. Alcoholics must be entirely discontinued, the excretions stimulated by calomel, salts, and Turkish baths, the usual quantity of morphin being continued till noon of the appointed

day. At 2 p.m., five drops of a solution of mandragorin is given hypodermically with an eighth grain of pilocarpin; this may be increased till comfort ensues. Strychnin and spartein may be given for cardiac weakness, and other symptoms be treated as they arise. The mandragorin is continued for 72 hours. The strength of the solution is not given by the writer. [H.M.]

Medical Record.

1. Acute Infectious Osteomyelitis of the Spine and Acute Suppurative Perimenigitis. J. RAMSAY HUNT.
2. Observations upon the Protective Value of the Inspection of Public Women as Carried Out in Paris. FREDERIC GRIFFITH.
3. Some Points on the Diagnosis and Drug Treatment of Pneumonia in Infants and Young Children. LOUIS FISCHER.
4. Prophylaxis of Puerperal Sepsis. GEORGE L. BRODHEAD.
5. Preliminary Notes on Transillumination of the Stomach with Fluorescin. H. W. LINCOLN.
6. Supplementary Note on a Case of Typhoid Spine. LEONARD W. ELY.

1.—Acute Osteomyelitis of the Spine, with Acute Suppurative Perimenigitis.—J. Ramsay Hunt calls attention to the rarity with which infectious osteomyelitis attacks the vertebral column. He reports two cases. The first is summarized as follows: Boy, aged 18. Sudden onset with severe pains in sacral region, following a trauma. High fever, rapid pulse, great prostration, leukocytosis 40,000, splenic tumor, edema, and boggy over sacrum. Symptoms of compression of cauda equina. *Diagnosis:* Acute osteomyelitis of the sacrum with an extradural accumulation of pus. Operation, cure. The second is summarized as follows: Boy, aged 5 years, previously healthy. Sudden onset with fever and severe pain in middorsal region. Five days later, symptoms of spinal cord compression (paraplegia). High fever, great prostration, leukocytosis 40,000. Slight edema, glazing of skin and boggy, with extreme tenderness over the middorsal region of the spine. *Diagnosis:* Primary vertebral osteomyelitis with an extradural accumulation of pus. Operation, cure. Hunt reviews extensively the literature on this subject. The abrupt onset in a young adult of intense local vertebral pain and tenderness with increasing symptoms of infection should always suggest the osteomyelitis. The prognosis of acute vertebral osteomyelitis is grave. Of 62 cases, of which 50 were operated, 30 proved fatal. The statistics of cases recorded during the past 5 years are more favorable. Of 28 cases, all but 2 of which were operated, there were 20 recoveries. [A.B.C.]

2.—Value of the Inspection of Prostitutes in Paris.—Frederic Griffith writes at length upon this subject. He states that a complete department has been established under the direct supervision of the Prefecture of Police, with a chief, a corps of inspectors, both police and medical, with assistants. One-half of a city prison has been set aside as a detention hospital, having over 200 beds, and inspection offices and a dispensary are maintained. Here every actively engaged prostitute in Paris is supposed to come for examination. Every interest of the woman is protected by the government supervisors. A third arrest brands the woman as a professional prostitute. Her name is listed upon the department record. A small photograph of the girl is taken and glued to a card upon which is written the individual's name, address, and date of registration. The card is given to the girl, she is directed to return to the dispensary for medical examination at intervals of 15 days under penalty of imprisonment. The French inspection system is to a greater or less extent the pattern for St. Petersburg, Berlin, and Vienna, and there is a growing tendency for cities in our country to look toward it as being probably the best solution of our own municipal social questions. [A.B.C.]

4.—Prophylaxis of Puerperal Sepsis.—G. L. Brodhead thinks that outside of hospitals, puerperal sepsis is about as common as before antiseptic methods. Since it has been conclusively shown that the vaginal secretion of healthy women is absolutely free from pyogenic cocci, the cause of sepsis must necessarily be the introduction of septic material from without, and that as a rule the germs are carried in on the examining finger, and thus the internal or vaginal examination during labor is directly responsible for a large number of deaths as well as a vast amount of suffering and invalidism; and Brod-

head believes that in teaching antepartum and intrapartum diagnosis by external manipulation lies one of the greatest safeguards against puerperal infection. In his own practice he has demonstrated over and over again that labor can be successfully concluded with no vaginal examination whatever. But if internal examination is necessary, as it is under some circumstances and complications, then he uses the following method of sterilization as advocated by Stewart of New York: For the vulva use a solution of chlorinated lime, one teaspoonful, and acetic acid (U. S. P.) two teaspoonfuls to the quart. For the hands, after cleansing with soap, water, and powdered pumice stone, he uses chlorinated lime, two teaspoonfuls; acetic acid, four teaspoonfuls, and water to make one quart. The hands are immersed for five minutes in this solution, they are then rinsed off in a 1% lysol solution, after which rubber gloves are worn. [W.K.]

5.—Transillumination of the Stomach with Fluorescin.

—H. W. Lincoln states that transillumination of the stomach, employing a solution of fluorescin, dates only since October, 1903, when Kemp introduced the measure. He has employed this method in a number of instances and is satisfied with the result. It may be used in stout as well as thin persons with good results; even in the colored race the results are fair. The method employed is as follows: Give the patient 10 gr. or more of quinin during the day of examination or the day previous. Introduce the lamp. Have the patient drink a glass of water, into which has been dissolved 30 gr. to 40 gr. of sodium bicarbonate, to render the gastric contents alkaline. Allow another glass of water to be taken, into which has been placed $\frac{1}{2}$ gr. of fluorescin, 1 dr. of glycerin, and 20 gr. or more of sodium bicarbonate. The abdomen being bared, conduct the patient into the dark room, or, if at night, simply turn out the lights. It is better to introduce the lamp before the solution, so that should there be any trouble, the fluorescin will not be vomited. [A.B.C.]

6.—Supplementary Note of a Case of Typhoid Spine.

—Leonard W. Ely, in the *Medical Record* of December 20, 1902, reported the present case. He stated then that the patient was going about wearing his brace; further statements with reference to the case are as follows: Soon after the report the patient undertook active work and began to leave off his brace. Pain in his back became worse and lateral curvature more pronounced. He applied to Dr. Gibney for treatment, and this consisted of the thermocautery 2 or 3 times weekly, and of the brace, which was worn during the entire 24 hours. At the end of 6 weeks the cautery was stopped. After 4 months the brace was left off altogether and with the exception of some weakness, the only symptom remaining consisted of occasional attacks of cramp-like pain occurring at increasing intervals, and ceasing altogether after 2 or 3 months. The whole duration of the disease was about 18 months, which agrees well with the accounts of the cases heretofore published. An examination by Dr. Gibney, several months ago, showed that the only visible remnant of the affection was a slight lateral curvature. [A.B.C.]

7. On Laboratory Diagnosis. M. P. OVERHOLSER.
8. Are the Antidotal Effects of Alcohol, Glycerin, etc., upon Carbolic Acid, Chemical or Physical? PHILIP ASHER.

1.—Ureteral catheterism as a routine method of diagnosis in renal disease is discussed by John Van Der Poel. He says there is no doubt but that when it is possible and practicable, the results are far more accurate and certain than by any other method. The advantages of catheterism over the other methods are expressed as follows: 1. The cystoscope is more easy of introduction than are the separators or segregators, is

less painful during the bladder manipulations, and much less so during the collection of the urines. Hence, as a rule: 2. With ureteral catheterism we can collect the urines during as long a time as may be thought necessary, the patient not requiring any supervision. 3. A cystoscopic examination of the bladder can be made at the same time, which, in some cases, is useful, in others, indispensable. 4. We are much more certain of the exact results, especially when the two urines are of a similar character, whether clear, bloody, or purulent (Albarran). 5. It is the only method by which we are fairly certain that there is no bladder contamination. [C.A.O.]

2.—See *American Medicine*, Vol. VI, p. 693.

3.—Retrouterine Hematocoele.—W. C. Gayler gives the results of a reexamination of 36 women who had suffered from a retrouterine hematocoele, and had been treated according to the various methods now in vogue. Thirty-three were caused by tubal abortion, two by tubal rupture, and one was caused by an escape of menstrual fluid into the abdominal cavity. Laparotomy was performed on 18 of the 36 patients. One died of sepsis, 15 were absolutely well at the end of four years, and two still complained of pains and discomfort in the pelvis. The average time until the complete recovery of the 15 who did recover was six weeks. The three who had been operated upon by way of the vagina were absolutely well. The period of convalescence was short, and two had again become pregnant. The conservative treatment consisted of rest in bed, liquid diet, and application of warmth to the abdomen. Only 13 of the 15 patients who were treated conservatively returned for reexamination. Eleven were free from their complaints, and showed no abnormalities. Two still complained of pain, a feeling of fullness, and pressure in the pelvis, and had a decided resistance in the culdesac upon internal examination. The average time that these patients stayed in the hospital was 20 days. [C.A.O.]

4.—Multiple Neuritis.—F. H. Stephenson reports a case of multiple neuritis which he believes to be due to morphin toxemia of 12 years' duration or to the possible poisoning from the so-called gold cure medication. The major items upon which the diagnosis was made were the motor and sensory symptoms, their symmetric distribution, their predominance in the extremities, the marked affection of the extensors, the modification of the reflexes, cold extremities, tenderness, aching and cramping sensations in the calf of the leg and toes after walking; also when holding the limb extended. The patient was directed to remain in bed or in a reclining chair much of the time. For the toxic condition and its attendant anemia large doses of the tincture of iron chlorid and salol were employed, also a nutritious diet, with oil rubs, sun baths and eliminatives. In the early stages hot applications gave great relief to the pain; others get greater relief from the cold. Gentle stroking or kneading of the muscles is very grateful to these patients, and aids return circulation and local nutrition. In some of the cases nitroglycerin seems to have a specific effect. [C.A.O.]

5.—Prognosis in Epilepsy.—After an experience of 14 years in the daily care and treatment of 1,800 cases of epilepsy in persons of all ages, types, conditions and degrees of duration of the disease, W. P. Spratling arrives at the following conclusions: 1. Epilepsy is curable in from 5% to 10% of all cases. 2. It requires, as a rule, a long continued course of treatment—never less than two to three years, carefully mapped out and executed to the letter, not only along one, but along many lines, to effect a cure. 3. The failure to secure better results, generally, in the treatment of this disease must frequently be laid to the failure to treat the individual and his disease as a unit, and to treat them both along the very broad, comprehensive, and unyielding lines they both require. 4. The drug treatment of epilepsy alone, while invaluable in many cases, and of some use in every case, often fails completely to meet the most important requirements. 5. Guides to the prognosis in epilepsy are always uncertain and unsatisfactory until treatment has been in operation from 6 months to 9 months, and in some cases a year or longer. The remarks pertain largely to the facts grouped about a series of 34 cases cured at the Craig Colony. In 20 cases the disease developed before the tenth year; in 9 between the tenth and twentieth years; and in 4 between the twentieth and fortieth years, while it commenced

in one only after the fortieth year. Twenty-three of them had grand mal attacks alone; 7 had grand mal and petit mal attacks combined; 3 petit mal only, while 1 had hysterio-epileptic convulsions of great violence, with occasional attacks of grand mal, uncontaminated by hysteria. The average duration of treatment for the whole number was 35½ months. Thirteen of the 34 cases had suffered from epilepsy from 1 to 5 years; 10 from 5 to 10 years; 7 from 10 to 20 years, while 4 had it 20 years or more. [C.A.O.]

6.—Ergot in Typhoid Fever.—A. T. Livingston urges the immediate and continued use of ergot in typhoid fever. He believes the peculiar function of this drug to be the stimulating, toning, and strengthening of whatever unstriated fiber is weak, relaxed, stretched or paralyzed. The solution of ergot which he finds the most satisfactory for hypodermic use is made by dissolving 1 dr. of solid extract of ergot in 1 oz. of sterilized distilled (cooled) water. After filtering the solution, add 2 m. of chloroform. The dose is ½ dr. to 1 dr., which may be given from 2 to 6 times a day, or oftener, as indicated in the individual case. [C.A.O.]

8.—Antidotal Effects on Carbolic Acid.—Philip Asher has made a number of experiments to determine whether or not the antidotal effects of alcohol, glycerin, etc., upon carbolic acid were chemic or physical. He found that the physical or chemic properties of the various factors used were never affected, and consequently chemic change never occurred. The antidotal power possessed by alcohol and glycerin depends largely upon the state of dilution. In addition to that of dilution, alcohol possesses dehydrating and astringent properties, which prevent absorption of the acid by the tissues. [C.A.O.]

6. Hookworm Disease and Miners' Anemia in the Anthracite Coal Fields. JONATHAN M. WAINWRIGHT and HENRY J. NICHOLS.
7. When and How Shall We Operate for Obstructing Hypertrophy of the Prostate Gland? PAUL THORNDIKE.
8. Reflections on the Surgery of Prostatic Hypertrophy. JOHN G. SHELTON.

2.—The Pulse as a Guide to the Life Insurance Examiner.—R. H. Babcock finds that life insurance companies do not lay particular stress on pulse tension; a persistent rate of more than 85 is considered a barrier. A rate of 100 is normal to some—generally those of a neurotic temperament. It may be due to vagus inhibition or stimulation of the accelerators by coffee, tea, tobacco, or alcohol. The most annoying cause of tachycardia is the psychic disturbance attending the examination. Under the influence of frequent contractions the apex beat becomes feeble and ill-defined, the first sound is murmurish. Other signs of nervousness must be noted. An excited heart does not show as marked contrast between rest and exercise as in cardiac inadequacy. Only exceptionally is pressure increased by psychic disturbance. Increase of tension and acceleration are generally combined in pathologic disorders of the myocardium. Tachycardia may also be due to pyrexia, heart syphilis, irritability from athletics, masturbation, or venereal excess, to convalescence from acute disease. When combined with high tension in a man of middle age with corpulent abdomen, it is of weighty import. Such an individual is not a good risk. A rate below 60 often indicates fatty degeneration, though it may be normal. When the person is elderly, look for arteriosclerosis. Lowness of blood-pressure in a person of middle age is a sign of cardiac weakness. An intermittent heart-beat is due to vagus inhibition by gastric, psychic, or other disturbances. An intermittent pulse may be due to feeble heart-beats from altered blood or muscle fibers. Irregular pulse-beats under exercise indicate myocardial weakness. [H.M.]

3.—External Diseases of the Eye from Rheumatism.—R. Kalish describes a marginal blepharitis of the young adult,

recurrent styes and chalazia, a circumscribed bulbar conjunctivitis, and striated keratitis, resisting other forms of treatment and yielding to rheumatic remedies, such as salicylates, iodide, baths, massage, etc. [H.M.]

4.—Spontaneous Rupture of the Spleen.—Charles F. Craig reports two cases occurring at the U. S. Hospital at the Presidio, San Francisco. He calls attention to the extreme rarity of this condition in temperate climates; it is said to be most frequent during malarial infections or in persons suffering from typhoid relapsing fever, and occasionally in leukemia. The first case was in a man of 23, a returned soldier from the Philippines. He was admitted to the hospital suffering from typhoid fever; the disease pursued the normal course, and three weeks after admission his temperature was normal; suddenly he complained of severe pain over the abdomen, especially the left hypochondrium, and on the following day collapse appeared, but not of a severe character. The condition persisted until the fourth day, when the patient died. Autopsy revealed a distinct laceration of the capsule of the spleen, and much blood in the vicinity of that organ. The rupture was without doubt spontaneous. The second case was in a man of 60, who had suffered from malaria for 15 years, and had used alcoholics for 25 years. He dated his present illness from a fall, for which he was confined in the hospital three months; suddenly it was noticed that respiration became difficult, and death occurred. He had become considerably emaciated before death. Autopsy revealed malignant disease of the liver, with metastasis of the lungs, and the ruptured spleen later, he believes, was due to pressure upon it by the enlarged liver. It was spontaneous in the sense that there was no sudden violence to account for it. [A.B.C.]

5.—Renal Tuberculosis.—F. Tilden Brown discusses the early symptoms of this affection. The patient, usually from 20 to 35, generally complains first of frequent micturition; often the disease is hereditary. Previous personal history usually shows more or less ill-health, with occasional mild febrile attacks; the patient is generally poorly nourished; the urine, which may be of abnormal appearance, should be thoroughly examined, and a small amount of pus or blood may be found; tubercle bacilli should especially be looked for. Unilateral tuberculosis having been diagnosed, the question of treatment is uppermost, but in the majority of cases the best prognosis lies in nephrectomy and, if possible, a change of air and improved hygiene should anticipate the operation. Nephrectomy for tuberculosis should always be done extraperitoneally; whatever the general procedure of the operation may be. A general description of the operation, treatment of the ureter, the pedicle, etc., are given. [A.B.C.]

6.—Hookworm Disease.—J. M. Wainwright and H. J. Nichols trace the spread of the parasite from one country to another in Europe through the mining regions. This is accounted for by the life history of the worm and the sanitary conditions of the mines. Coal dust has been used experimentally in developing the ova. None of the anthracite mines in this country, and only a few coal mines in Europe, have any privy facilities under ground. The men deposit excreta anywhere. The eggs are transmitted from the boots to the hand and thence to the food, the worker eating his dinner in the mine without washing his hands. The disease is widespread in our Southern States and our recently annexed islands. Stiles drew attention to the economic meaning of the parasite known in the lay press as the "bacillus of laziness." The worms live in the human host for six years. The writers, in examining 400 anthracite miners, found only one case, showing that the hookworm has not obtained much foothold among anthracite miners as yet. All mine mules are infected with an organism closely allied to the human parasite, but these are probably not transferable. No aid in keeping out the disease can be expected from the miners. The State Bureau of Mines or Health should have the stools of newly employed miners carefully examined. [H.M.]

7.—Prostatic Hypertrophy and its Treatment.—Paul Thorndike writes at length upon this subject, and concludes as follows: (1) The catheter has as wide a range of usefulness as it ever had, in the palliation of obstructing prostatic hypertrophy; (2) the various operative procedures at present at our

command are to be resorted to, with the exception of certain small classes of cases referred to in these remarks, after the catheter has ceased to palliate; (3) the time for this operative interference is at the moment when the catheter has ceased to palliate, and not after months or years of further and unavailing struggle to make it do so; (4) the more radical operation of enucleation, on the one hand, and the Bottini operation with its various modifications on the other, are not procedures of the same kind, do not have the same object in view, and are in no sense to be weighed in the balance, the one class against the other. They should rather be contrasted, the one class as radical operations aiming at a cure, and the other as efficient palliating procedures, each having its own distinct indications for its appropriate use. [A.B.C.]

8.—Surgery of Prostatic Hypertrophy.—John G. Sheldon considers patients suffering from this affection in two classes: (1) cases in an extreme condition, and (2) cases with sufficient vitality to withstand a radical operation. In the latter variety he performs perineal partial prostatectomy. The operation he describes at length, reporting 11 cases in which operation was performed. He concludes as follows: 1. Infection is the all-important consideration in prostatics. 2. Perineal drainage of the bladder relieves the patient. 3. Many of these patients will not stand extensive operative procedures or long continued anesthesia. 4. Partial removal of the prostate, by the method herewith advised, will be tolerated by many infected patients, and a good result obtained. 5. Perineal drainage of the bladder only should be done in desperate cases and in debilitated patients in whom morcellation is necessary. In these cases, the prostate should be removed at the second operation. [A.B.C.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

REVIEW OF LITERATURE

Early Diagnosis of Acute Intestinal Obstruction.—W. Hale White¹ differentiates acute intestinal obstruction from acute hemorrhagic pancreatitis, perforation, or rupture of the various hollow viscera, or cysts within the abdominal cavity, thrombosis and embolism of the mesenteric vessels, intestinal colic, twisted or ovarian cysts, ruptured extrauterine fetation, and ruptured pyosalpinx. It is of importance to remember that the early symptoms of acute intestinal obstruction are caused by strangulation, and not by obstruction. This is illustrated by the fact that volvulus of the large intestine gives sudden and acute symptoms because of strangulation, while the symptoms of a complete obstruction, as by gallstone without strangulation, are much less severe. It is further illustrated by the fact that in many recorded cases fecal impaction has existed for weeks, and even months, without causing marked constitutional disturbances. To make a correct diagnosis of the form of obstruction which exists, if the symptoms are severe and acute we are to remember that it is the picture of strangulation as from a band, internal hernia, volvulus, or kinking, and not from mere obstruction. The severity of the symptoms of intussusception depends upon the portion of the bowel strangulated; obstruction in the small intestine produces more marked symptoms than obstruction in the large intestine, because whatever obstructs the small intestine at the same time usually strangulates it. [A.B.C.]

The Influence of Complicating Diseases upon Leukemia.—George Dock² reports a case, of which he gives the following summary: A woman with mixed-cell leukemia, with greatly enlarged spleen. Two weeks after an attack of what was probably influenza, the leukocytes dropped from 367,070 to 7,500, in two weeks more to 4,775, with reduction of abnormal red and white cells. The spleen was much smaller. In two months the leukocytes reached 40,000, in 10 weeks 157,000, in a year 461,666. The liver and spleen remained small for many months; for the next six months the patient grew worse, and died one and a half years after the first observation. Dock reviews the literature at length in an endeavor to deter-

mine the effect of infections, and of processes other than infection upon the course of leukemia. In general, there is a tendency for the leukemic character to disappear more or less completely under the influence of infections, the fall in leukocytes occurring soon after the infection, more promptly in acute than in chronic infections. The conclusion reached is that a satisfactory explanation of these changes is not at present possible. As to treatment, Dock suggests that as the ordinary treatment is hopeless, carefully planned experiments, either with bacterial products or organ extracts, might show a more safe and permanent result. [A.G.E.]

Epidemic Catarrh on Shipboard.—Dudley N. Carpenter¹ reports that on the battleship Illinois, manned by some 700 men, a series of catarrhal fevers were several times observed. During the epidemics the majority of the cases were of a respiratory type, beginning suddenly with pain in the back, head and limbs, chilly sensations, marked constipation, weakness, anorexia and fever. Among the complications pleurisy, peritonsillar abscess, otitis media, and arthritis occurred. Carpenter says there was undoubtedly a contagious factor producing these catarrhal fevers, but at the base of the trouble he believes that poor ventilation on shipboard was the most potent cause. The influence of overcrowding and poor ventilation has often been observed in camps, asylums and public institutions, and it is particularly objectionable on shipboard. [A.B.C.]

Concerning Infantilism Independent of the Thyroid Gland.—L. Ferranini² insists that Lorain's infantilism is not the same as the infantilism of Brissaud or myxedematous infantilism. The former is a small man with impeded or incomplete development, the latter is an individual, whose development has ceased with early childhood, in the former ossification is complete, in the latter it is imperfect. Lorain's infantilism has nothing to do with dwarfism. In it the different parts of the body are proportionate, but smaller than the age would lead us to suspect; in it the beard, axillary and pubic hairs are missing, the genitalia small, the intelligence normal. Brissaud's type is that of myxedema and is often helped by thyroid extract, while Lorain's type is not improved by it very much. The causes of infantilism are such as produce physiologic weakness, infections, intoxications, nutritional disturbances and conditions predisposing to disease. He reports cases in which the condition was traced to tuberculosis, hereditary syphilis, malaria, alcoholism in parents, and congenital heart disease. He studied carefully the metabolic processes observed in a case, in which the infantilism was due to congenital mitral disease, and states that the conditions corresponded to an age actually less than that of the patient. REVIEW OF LITERATURE

Spontaneous Gangrene of the Hollow Viscera.—Roswell Park³ reports in detail two patients suffering from pronounced abdominal symptoms, such as severe pain, vomiting, distention of the abdomen, constipation, etc. In each case laparotomy was performed, and in each instance widespread gangrene of the intestine and other viscera were noted; in neither was autopsy permitted. An extensive discussion as to the probable etiology of the condition is entered into, particularly the probability that mesenteric occlusion by thrombosis of the vessels or simple emboli in the same may have been responsible for the condition. Park recounts and discusses the symptoms at length and differentiates between the condition described and that presented by perforating ulcer of the stomach, acute intestinal obstruction, pancreatitis, acute splenic infarction, acute appendicitis, acute cholecystitis, ruptured extrauterine pregnancy, and intrathoracic lesions. He emphasizes the statement, that in the presence of sudden and acute symptoms, with acute intense abdominal pain, collapse and rigidity

of the abdominal walls, there should be no speculation as to the character of the lesion, the triad of symptoms constitutes a reliable and exacting demand for abdominal section. [A.B.C.]

Spinal Anesthesia in Military Surgery.—Colonel Augustin A. Guirre,¹ writing from the Military Hospital of Instruction of the city of Mexico, reports a series of 210 cases operated upon by spinal anesthesia. He introduces the fluid exactly in the middle line below the spinal apophysis of the third or fourth lumbar vertebra, or even below the first, instead of going to one side and entering the needle obliquely. Clotting of the introduced needle is avoided by rapid introduction and having within the needle a wire mandril, which is removed after the needle is introduced. In 5% of the cases anesthesia was not sufficiently painless to perform operation; in 11% of the cases there were accidents caused by the introduction, though in no instance was there a fatal outcome. These accidents were such as vomiting, nausea, acceleration of the pulse, and convulsions (in one case). Anesthesia lasted from one hour to one and one-half hours. The advantages of this method, according to the author, are: (1) Easy application, as the operative manual required does not present many difficulties; (2) the possibility of its being performed by the surgeon himself, which does away with the services of an assistant; (3) speedy action; (4) safety, no fatal result was recorded in his series; (5) a simple apparatus, easily carried and easily sterilized. [A.B.C.]

Operation on the Spinal Cord.—Samuel J. Mixter and Henry M. Chase² report two cases. A summary of the first is as follows: High fracture of the spine, sixth cervical vertebra; there were present all the classic symptoms on which authorities have previously based their opinion that operation was contraindicated because it suggested total transverse lesion with a crush of the cord beyond repair. The patient was operated upon within 24 hours; operation showed fracture and depression of the spinous process and laminae apparently lying against the cord. There was a blood clot under the lamina, none under the dura. The condition of the bodies of the vertebra were not known. The patient lived 11½ months, during which there was marked and steady improvement from a condition of almost total paralysis of the entire body below the seat of injury. The patient regained nearly the normal use of his hands and much improvement in the condition of his body and legs. Complications arose and the patient died. Microscopic examination of the cord removed postmortem are given in detail. The second patient sustained a similar injury in the cervical region and showed marked paralysis. Following operation, he has almost recovered the normal use of the affected parts. The authors insist that patients sustaining such injuries, even though they point to complete solution of continuity in the cord, should be operated upon, because a definite diagnosis of such a condition can not be made with certainty. [A.B.C.]

Malignant Disease Observed in a U. S. Army Hospital.—Col. Alfred C. Girard³ reporting the cases from the U. S. Hospital at the Presidio, San Francisco, states that most of the cases occur in young able-bodied men with no family history of malignant disease. The etiology of the cause in almost every instance was some injury to the affected part. The cases described occurred during the period between July 1, 1899, and May 1, 1902. Of the fourteen cases there were eight due to carcinoma, and six to sarcoma. Of the cases of carcinoma, two were operated upon, both recovering, and six were inoperable. In six cases of sarcoma all were operated upon, five recovering. The cases of sarcoma were as follows: Sarcoma of the mesentery, of the popliteal space, of the breast, of the testicle, (two cases), and of the femur. The cases of carcinoma were as follows: Carcinoma of the breast, epithelioma of the jaw, carcinoma of the larynx, of the bladder, of the omentum and abdominal viscera (two cases), of the liver and other viscera, of the pancreas and spleen. Gordon states that the point of practical importance appears to be the great difficulty of recognizing a malignant process within the abdominal cavity before the case becomes practically inoperable. [A.B.C.]

TREATMENT

SOLOMON SOLIS COHEN

L. F. APPLEMAN

E. LINDAUER

REVIEW OF LITERATURE

Treatment of Ozena with Injections of Hard Paraffin.—Noticing that ozena is oftener found in an abnormally large nasal cavity, which offers splendid opportunities for the accumulation of crusts, than in a narrow passage, H. Fliess¹ attempted to imitate nature by injecting paraffin into the inflamed meatus, thus making the passage much narrower. All crusts were first carefully removed, the infected meatus, nasal floor, and septum cocaineized, and the atrophic mucous membrane injected with paraffin. Usually the lateral portions were treated, sometimes the septal walls also. Twelve patients were thus treated, and in all the results were better than had ever been produced by any other treatment. A complete cure did not result in any of them, but the crusts disappeared altogether, and also the bad odor. No unpleasant complications were noted. On account of the danger of pulmonary embolism from the use of soft paraffin Fliess employed hard paraffin altogether. [E.L.]

Alcohol Poultices.—J. S. Kolbassenko² recommends an alcohol poultice in all surgical inflammations and suppurations. He considers it a very active analgesic, and has found that if used early, suppuration is very often aborted, while at a later stage its use results in localization of the abscess to its original focus. Six to eight layers of gauze are kept saturated with 50% to 95% alcohol, and to prevent undue evaporation this is covered with a layer of oil cloth. When the skin is tender, or if ulcerated surfaces have to be treated, xeroform powder or xeroform-orthoform ointment, or sterile vaselin may first be applied to the surface. The dressings should be continued until hyperesthesia has disappeared from the inflamed area. The action of this dressing is noted not only in superficial disturbances, but also in inflammations of the deeper-lying tissues and organs. Kolbassenko has also seen good results from the dressing in phlegmonous angina and in early scarlet fever; in both diseases the applications having been made to the neck. [E.L.]

Treatment of Acute Nephritis.—A very simple, efficacious method of treating acute nephritis is according to L. Stembo,³ by ice. Favorable results in two very grave cases caused him to use it systematically in 20 cases of nephritis which came under his observation during a scarlet fever epidemic lasting 18 months. It shortened the duration of the illness markedly in all cases. Long narrow ice-bags are filled with small pieces of ice and tied firmly over the region of the kidneys, the patient lying on his side. It is removed after two or three hours, and replaced one hour later. Flannel may be interposed between the ice-bag and the skin in very sensitive people. He also employed it with success in exacerbations of chronic nephritis. He explains the marked success of the treatment through relief of the congestion in the diseased and enlarged kidneys; this relief is produced quicker than with heat, which acts indirectly through hyperemia of the skin, producing anemia of the internal organs and therefore also of the kidneys. [E.L.]

Treatment of Articular Rheumatism with Menzer's Antistreptococcic Serum.—A. Schmidt⁴ employed Menzer's antistreptococcic serum in 15 cases of articular rheumatism; 8 were of the subacute variety (many measures were tried without result), 4 were acute and 3 chronic. The injections (15 cc. to 20 cc. daily) were made into the joints and were repeated in 8 days. The more pronounced the reaction (redness, swelling, erythema, etc.), the more certain is the curative success. Local reaction must therefore not be considered an injurious side-effect. Six patients were decidedly improved; in 4 there was subjective betterment, and in 5 no result was noted. A specific action, as with diphtheric serum, was not obtained. He recommends the treatment in subacute cases, when other remedial agents fail. [E.L.]

PUBLISHED WEEKLY AT 1321 WALNUT STREET PHILADELPHIA BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. VII, No. 19.

MAY 7, 1904.

\$5.00 YEARLY.

Water meters should be placed in every house and building of every city. This is demanded in the interest of the health of the people. The reckless waste of water is making it more and more impossible to give pure germ-free water to every household, and the wasteful use constantly deteriorates the quality of that which can be supplied. The partially filtered water gives a feeling of false security, and thus becomes more dangerous than that which is black and polluted. It has been proved almost impossible to get everybody to boil the water used even when it is plainly fouled, but when it is apparently pure but in reality germ-laden, the apparent security at once increases the number of cases of typhoid. There is no reason against, and every consideration of justice urges the measuring of the water used just as much as in the cases of gas or electricity.

Three hundred and twenty-one new cases of typhoid fever in one week in "corrupt and contented" Philadelphia, should arouse her citizens to the infamy of the crime which has brought about such a condition. Since the first of January there have been over 2,000 cases. In England, in 1901, there was a deathrate from typhoid fever of 1.55 per 1,000,000; in Paris, 3.91; while in Hamburg the rate was only .33. It is an old saying that for every such death someone should be hanged, but the fatalism which has from of old dominated the human mind as to disease and death is still inveterate, and it is almost impossible to arouse the truer perception that every case of typhoid fever represents, in reality, a crime somewhere, and somebody has been guilty of criminal negligence, which should be brought home to him. Every case, as we all know, is unnecessary, and unnecessary disease and death is in its last analysis a crime. In our modern communities it is not difficult to place the blame where it belongs, but it is a very different matter to bring to punishment the criminals. At first sight it would seem that the political wretches, the swearing, drinking thieves, and bosses, placed in power over the health and lives of the citizens are to blame. But at once arises the second sobering thought that the citizens are more blameworthy who give these fellows their ill-used power.

Domiciliary Health Records.—Beside supervising the production of milk and meat, examining wet-nurses, attending to school hygiene, dismissing tubercu-

lous soldiers from the army and disinfecting their apartments, placing cuspidors for general use, registering all cases of tuberculosis, disinfecting houses in which these have occurred, isolating the poor tuberculous in hospitals, instituting obligatory insurance against disease, and establishing tuberculosis dispensaries, Bernheim¹ recommends special medical supervision over dwellings and the use of a health book for houses. The instituting of such a book, dealing with the records of dwellings, seems to us to be a particularly wise procedure. In addition to furnishing valuable statistics on a large scale, it would result in more intelligently dealing with the vast problem of tuberculosis. As Flick, in his pioneer investigations, has shown, tuberculosis clings to certain houses. The same has been said to be true of cancer. If, through a book, or preferably, a card system, the municipal health office, should keep records of all the deaths that occur in every private house in Philadelphia, valuable information would be accumulated in the course of a few years. Deaths occurring in hospitals could be recorded on the cards belonging to the houses from which the patients had come. The simplest plan would be to make out a card for every house as soon as a death takes place in it, and to record thereon all subsequent deaths occurring in that house. Anyone desiring to learn whether in a certain house or a particular street there have been many deaths from tuberculosis, cancer, or any other chronic disease, could very easily obtain this information by consulting these records. A system of cross references would make it possible by looking under the heading of any particular disease to determine in what part of the city that disease is most common.

Arctic Sanatoriums.—The advantages offered by the three months of Arctic summer are so numerous, that there have appeared recently several announcements of floating and permanent hospitals for patients suffering from incipient pulmonary affections and neurasthenic states. According to the *British Medical Journal*, it is proposed to erect a sanatorium on the shores of Lake Torne, in Lapland, a long and beautiful sheet of water at Wassijauve, near the end of the Ofote Railroad. That railroad, it may be mentioned, has only one station in a distance of 121 miles. There is no

¹ La Rev. Philanthr., viii, 43, p. 27; Hyg. Rundschau, April 1, 1904.

human dwelling near that station, which is on the line between Sweden and Norway, and was erected solely for the requirements of the Customs Office. Except for a small settlement at Wassijauve, the only sign of human existence in the district is the occasional passage of a few Laplanders with their herds of reindeer. Already, there has been installed at this spot a scientific station in a solidly built block-house containing seven rooms, and it is proposed to build the sanatorium in the same way. In *American Medicine*, April 23, 1904, Dr. Frederick Sohon has called attention to the great advantages of the Arctic climate. We learn that Dr. Sohon has decided to organize a cruise to the fjords of Greenland, leaving in June, and returning before the hardships of the Arctic winter begin. These regions of perpetual sunshine may be reached within 10 days from Nova Scotia, and the trip may be made with safety and comfort in a suitable vessel altered and appointed for this purpose. Dr. Sohon would be pleased to communicate with any prospective passenger patients. His address is 512 I street, N. W., Washington, D. C.

The Mosely Educational Commission.—By the courtesy of the editor of the *British Medical Journal*, we are able to lay before our readers some of the principal conclusions reached by the medical members of the Mosely Commission as to medical education in the United States and Canada. In 1902 Mr. A. Mosely, impressed by the practical ability of American engineers, organized an industrial commission of British business men to visit the United States in order to find an answer to the question: "How is it that the United States can afford to pay half a dollar in wages where we pay a shilling, and yet compete with us in the markets of the world?" The answer turned largely upon the character of the education, using that word in its widest sense, available in the United States. In the autumn of last year Mr. Mosely arranged for an education commission to visit the United States with a view to studying the schools and universities. The subjects placed for investigation before this commission were:

1. The development of individuality in the primary schools.
2. The social and intellectual effects of the wide distribution of secondary education.
3. The effect of specific instruction given (a) in business methods; (b) in applied science.
4. The present state of opinion as to the value of professional and technical instruction of university rank designed with special reference to the tasks of business life.

The commission consisted of 26 persons selected for their special acquaintance with various departments of education in Great Britain and Ireland. The medical representatives were Dr. J. Rose Bradford, professor of medicine, University College, London, and Dr. W. H. Gaskell, university lecturer in physiology, Cambridge. Dr. Gaskell says that there is at the present time a feeling of unrest and uncertainty both in the United States and in Canada as to the best methods of instruction. Experiments are being tried, and he has evidently found it difficult to give any very decided general view.

The Teaching of Anatomy and Physiology.—Dr. Gaskell finds that in the universities of Harvard and

Johns Hopkins the student is first of all required to spend three to four years in an academic course for the degree of M.A., and is only then permitted to enter upon the medical curriculum of four years, at the end of which he receives the degree of M.D. This long period is recognized as a drawback, though the great advantage of a collegiate course is universally recognized, so that Dr. Gaskell believes that there will be a tendency more and more developed in the United States to institute a combined course of six years, which will enable the student to obtain his academic degree at the end of four years and his medical at the end of six, a system very similar to that in force in the universities of Canada and at Cambridge and Oxford. The system is already in working order in the more western universities of Chicago, Minneapolis, and Ann Arbor. Here the teaching of human anatomy and physiology is included in the scientific subjects for the scientific degree, and, in consequence, the laboratories for these subjects are built in close connection with those for the other scientific subjects, and not, as in most of the eastern States, in the midst of the town near the hospital, but far removed from the scientific buildings of the university. In this tendency of the universities of the Middle West not to divorce physiology and human anatomy from a list of subjects belonging to a science school and confine them entirely to medicine, he finds one of the most hopeful signs for biologic progress in the States, and he adds:

Such a subject as physiology especially ought never to be taught or studied except in close proximity to the laboratory buildings of chemistry, physics, and anatomy, both human and comparative. All the problems of physiology fall under one of these three heads, and where there is easy intercourse between the teachers and thinkers in these various subjects, there will be found the broadest views and the most efficient teaching power. When the scientific buildings of the university are situated many miles away from the medical school, and in the latter alone is provision made for teaching physiology and human anatomy, then such intercourse is very much hindered, to the detriment of both schools. I hope sincerely that in the new arrangements for the London University, the proposal to concentrate all the preliminary medical subjects, even up to bacteriology, into one more scientific schools apart from the hospitals, will be carried out.

Methods of Teaching Medicine.—Dr. Gaskell found that in many universities didactic lectures were looked upon as nearly valueless, on the ground that they were only a repetition of what was already in the textbook, and were not, therefore, needed. Dr. Gaskell sums up this part of his subject as follows:

The idea underlying the whole system of instruction in these scientific subjects is that they are subjects based on experimental research, that the question which the student ought to be taught to ask from the very first is not, What man is the authority for such and such a statement? but: What is the experimental evidence which proves the truth of the statement? Therefore, in every way the student is taught to consider that he himself is undertaking a research, that he is rediscovering for himself what others have found out before him. In accordance with this view no slovenly work is allowed; every experiment must be done as though it was an actual research, time markers, stimulation markers, being used, with the result, so I am assured, that in a very short time it becomes a habit in each man to perform every experiment with real care and thoroughness. Such a method of instruction necessarily means a large amount of time given to the subject, and a con-

siderable staff of efficient teachers to supervise the practical work and conduct the recitations, for the latter in order to be of real good must not be given to too large a class.

Dr. Gaskell then describes at length the Harvard "concentration system," a brief account of which is quoted below from Dr. Bradford's report. At Harvard the students are also required to prepare theses, which are read at fixed times and discussed in the class by students and teachers. This is an adaptation to an elementary class of the system of "seminars," followed in all advanced work in all the graduate schools for the degrees of Ph.D. and M.A. A seminar is really a discussion opened either by the teacher or by a member of the class in which all are expected to take part. This system, founded on the belief that the best way of learning is to teach, Dr. Gaskell regards as very valuable, though he questions whether it can with advantage be applied to a large elementary class. In some of the more fortunate universities, each student had a separate place entirely his own, but where this was not possible, the class was divided into sections, so that during the whole time each section was at work, the working places belonged absolutely to the members of that section. The whole system, Dr. Gaskell points out, throws a great strain upon the teachers, but he says:

To my mind, two of the most striking points about the laboratory instruction of all kinds in the States is the energy and activity displayed by the teachers, their earnest endeavor to do their utmost without sparing themselves, and the determination of the students to be taught. I do not think it is only because the practical work counts in their final examination that the men attend and work steadily, but because they want to get their money's worth; they have come to the university to be educated for the medical profession, and the stimulus of want or means spurs on a large number, with the net result that the class as a whole attends well, works well, and in consequence soon becomes thoroughly interested in what must interest everyone—the discoveries of science.

Laboratory Work in Medical Teaching in the United States.—According to the Mosely Commission Report, the greater number of subdivisions of the preliminary medical scientific subjects necessitates a greater number of well-equipped laboratories and a greater staff of teachers. Upon this topic Dr. Gaskell makes the following observations:

With respect to the first item, the building of laboratories, the activity going on in the States makes one ashamed of one's own country. Everywhere one has the feeling that the whole country is so impressed with the desire for the best educational methods that whenever new buildings are required the money is forthcoming for their erection. Either it is given by a munificent donor or is left by will, or is obtained from the past alumni and the general public by the exertions of the president. In the State universities matters may move a bit more slowly, but here, too, new buildings arise with considerable rapidity at the demand of the faculty. It is impossible to enumerate all the rooms for students and research in the different departments of all the universities visited; it is sufficient to say that at Harvard and at University of Pennsylvania it was felt that the laboratories for the preliminary scientific medical subjects were not quite up to date, and in consequence in both places palatial buildings are arising for the teaching of physiology, pathology, etc. The building at Philadelphia, which is nearly completed, will be, I should think, the finest in the world, unless the Harvard building beats it. At Chicago also there is practically unlimited space for buildings, and also an unlimited purse.

The laboratories in all the universities are found to be well equipped, and in some cases the laboratory unit system has been introduced and has given great satisfaction. He says:

The essence of this system is the limitation of the size of each room in which practical work is done. Instead of one large room holding places for 70 or 80 students, there are a number of small ones each with places for 25 students. Each room has its own demonstrator, and every student has his place during the course. The new laboratory for physiology and pathology at Toronto is built on this plan, and impressed me very much. The dissecting-room at Johns Hopkins is also divided in the same way, so that each room contains three bodies, and as there are seven students to a body, there are 21 students in the room under the charge of a demonstrator. A dissecting-room under these circumstances does not give the usual feeling of being overcrowded. There is an air of seclusion and quiet work such as one is accustomed to associate with a class of advanced students in English laboratories but not with a large elementary class. I am inclined to think that one of the most important lessons we can learn from Canada and the United States is how to treat a large elementary class as though its members belonged to a small select one. In order to carry out any such plan successfully, we must not only have the right kind of laboratories, but also a sufficient number of efficient teachers; each unit of the laboratory must have its own demonstrator, while the professor supervises and superintends the whole laboratory.

Lectures, Recitations and Examinations in Medical Teaching.—In his report, Professor Bradford says that in our country the general trend of opinion seemed to be in favor of curtailing formal and didactic courses of lectures, and in some universities they have been abolished altogether. In the case of medicine their place is taken by what is called the "recitation," which varies in value enormously in different schools. He gives the following description:

In some in the recitation the teacher meets a section of the class and a given subject is discussed between them, the teacher questioning the class and the individual members of the class frequently questioning the teacher. In fact, in many of the recitations it was very striking to see that the ordinary distinction between the teacher and the taught was very largely broken down, and that the teacher was, so to say, almost a member of the class. In such instances the recitation was based on a given subject which the class had previously read up in one or more textbooks. It is obvious that such a method of instruction has a very distinct educational value, particularly if the subject is selected judiciously. In other instances the recitation was based on a given textbook, and the class was informed at a previous meeting that at the next meeting pages so-and-so to so-and-so would be considered, and in the course of the academic year the textbook was gone through almost page by page by the class. The attendance at recitations was remarkably good, and the students were earnest and eagerly took notes. When the recitation was based on a textbook the recitation was really a means of ensuring that the student had made himself acquainted with the text, although, doubtless, in many instances the experience of the teacher enabled him to add to the information imparted by the book. The recitation in one form or another may be said to be universal as a system of instruction, and has to a great extent, and, in some instances, entirely supplanted the lecture. No very useful purpose can at present be served by comparing the examination systems in vogue in the States with those obtaining in England, as the conditions are so entirely different in that the degree granted by the universities confers no right to practise; the latter is obtained by passing a State examination under the supervision of a special Board. In all the universities the manner in which the student has followed his courses of instruction is a determining factor in deciding whether he shall or shall not receive a degree. Further, it is

very usual for the examination in each subject to take place at the end of the course of instruction in that subject, and hence the examination, particularly in what are called in this country the preliminary and early subjects, is to a large extent a piecemeal one. As regards the final subjects—medicine, surgery, and obstetrics—in some instances the student is examined in all at one time. The fundamental and far-reaching difference between the American and the English systems lies in the fact that the record of a student's work, recitations, laboratory classes, ward work, is kept, and very largely, and in some cases almost entirely, determines the result. A very prevalent custom is not to admit him to the written or practical examination, often held at the end of a course, unless the report of his class work is satisfactory. Such written or practical examination when held is conducted by the professor himself, but the report of the class work is made by the instructor or demonstrator in charge. All the student's drawings, laboratory notes, clinical records of cases seem to be marked and pigeon-holed. In many universities if the student is rejected in three branches he loses a whole year and the courses have to be repeated. It is difficult to form an estimate as to the number of students who fail, but in the leading universities the proportion would seem to be small compared with what obtains in England.

Conclusions of the Mosely Commission.—Dr. Gaskell makes the following suggestions:

1. In English medical and scientific schools separate laboratories with a separate staff of teachers ought to be provided for anatomy, histology, physiology, physiologic chemistry, experimental psychology, and perhaps neurology; such laboratories should be arranged on the laboratory unit plan and fitted up throughout with electric light, electric power, and telephones.
2. In cases where there is not sufficient accommodation for the whole class at once, the class should be divided into sections and the teaching so arranged that every student has his place to himself during the whole of that course.
3. I would not advocate the extreme concentration method of learning a subject, but would rather spread such a subject as physiology (in the English sense) over two years. In the first year I would give a general course, in which the subject should be treated as a whole in an elementary way, taking, therefore, together the histologic, chemic, and physiologic aspects of the subject, so as to give the student a good general view of the subject, and leaving the more detailed study to separate courses in the second year in the separate laboratories of histology, physiologic chemistry, and physiology.
4. I am inclined to think that histology should not be connected with embryology and put into the department of anatomy, but the laboratories of histology and physiologic chemistry should be under the control of a professor of physiology, the head of each department being an assistant professor.
5. I am not convinced that didactic lectures are in large measure a mistake, and that recitations should largely take their place. I think, however, that the system of seminars should be encouraged as much as possible.
6. A six or seven years' conjoint course for the academic and medical degrees should be encouraged as much as possible, and in all universities the preliminary medical scientific subjects should be included among the subjects for the degree in arts or sciences.
7. There is much to be said in favor of taking into account the work done by the student during the term in his examination. There are, however, so many difficulties in the way, owing to our system of examination, that it does not seem advisable to lay much stress on this point.

Professor Bradford's conclusions are:

1. That the enthusiasm of the teachers and of the students was one of the most striking features of my visit.
2. All the leading universities had exceedingly fine, and in some cases magnificent laboratories, and the equipment was of a high order of excellence.
3. In the teaching of the nonclinical subjects the laboratory and practical side was especially developed.
4. Systematic instruction by lectures seemed not to be in general favor.

5. Even in the final subjects (medicine, surgery, etc.) the teaching was extraordinarily systematized; but, speaking generally, the students did not have the clinical facilities they obtain in this country.

6. The scientific investigation of disease in clinical laboratories had reached a very high order of development.

7. The teachers in this country in such subjects as pathology might well consider whether some of the methods in vogue, such as the early study of bacteriology and the custom of giving the class unknown organisms and sections to identify, and the careful record of the students' work, are not features thoroughly deserving of imitation.

The Watercress: Its Virtues in Beriberi, etc.—The *Lancet* (February 20, 1904) announces the receipt from the Foreign Office of a copy of a dispatch from His Majesty's Consul at Noumea, New Caledonia, with reference to the mysterious disease, beriberi, which is very prevalent among the workers in the mines—of whatever nationality—in that island. Also, of a note on that dispatch by Sir Patrick Manson, medical adviser to the department. Mr. Haggard states that "it seems to have been found out quite accidentally that watercress is an almost certain cure. Consequently all the mining companies are cultivating it largely." Sir Patrick Manson suggested the immediate publication of the statement, with the judicious scepticism of the possibility of "inadequate experience." That this vegetable has a specific action on the germ of the disease I question. However, it is an experience worth following up. The publicity given by the medical press will insure this. Whatever may be the ultimate decision arrived at in this connection, there is no questioning the fact that the present boom of the watercress in that remote region is a specimen of the rediscovery of the medicinal value of an herb which was a famous remedy in ancient and medieval times; and whose traditional virtues, although forgotten to science, still lingered among the uneducated of many regions. In the remote districts of the British Islands, the watercress always maintained an exceptional reputation as a blood-purifier and an appetizer—especially when "taken in the morning fasting," and in "The New London Dispensatory," published by the famous herbalist, William Salmon, in 1684–1685, the properties and virtues of the "herb" in question are summarized as follows, page 81:

Nasturtium aquaticum, watercresses, hot and dry in 3°, they cut, attenuate, and open obstruction of liver, spleen and gall; are diuretick, lithoutriptick, alexipharmick and carminative: the Essence taken for 30 days, together three times a day, in Rhenish wine breaks and expels the stone, and perfectly cures the Scurvy and green sickness, and provokes the tears; they are a good Sallet, Winter and Summer, being boil'd: the juice only put into the nose often, cures the *polypus*, and being put in with Vinegar causes sleep: but when we mean the inspissate juice. If the herb be bruised with a little leaven and fermented, you may extract by distillation, an antiscorbutick spirit, prevalent to all the purposes aforesaid.

Guards Her Floating Ribs.—It is reported that a woman of Boston, 80 years old, and worth \$75,000, is hiding herself because she says physicians want her body to dissect, and all for the reason that her floating ribs have by muscular action been transferred from her right to her left side. She says that recently when she was in a hospital for treatment her malformation was discovered, and she was offered \$2,000 on condition that she would bequeath her body for dissection. She fears that the doctors won't be content to wait until she dies, and so she has concealed herself. Her malformation is said to be unique, in that it has been caused by gradual muscular action.

AMERICAN NEWS AND NOTES

GENERAL.

In the First Stage of Eddyism.—Every little while we read in the paper that someone has run a rusty nail in his hand or foot or other portion of his body, and lockjaw resulted therefrom, and that the patient died. If every person was aware of a perfect remedy for such wounds and would apply it, then such reports would cease. The remedy is simple, always at hand, can be applied by anyone—what is better, is infallible. It is simply to smoke the wound or any wound that is bruised or inflamed, with a woolen cloth. Twenty minutes in the smoke will take the pain out of the worst case of inflammation arising from such a wound. People may sneer at this remedy as much as they please, but when they are afflicted with such wounds, let them try it.—[From the Granite (Ore.) Gem.]

Agricultural Department and the Bordeaux Mixture.—It is not at all surprising to read now an official statement to the effect that the experiments conducted by the Department of Agriculture have nothing to do with the mixture referred to and that "these experiments have not reached such a stage as to be of benefit to the public." This was evident, but the statement relieves the Department of Agriculture from the imputation of ignorant quackery which the former dispatches conveyed. It is emphatically denied that the department has any process "to take the place of the present standard means of purification" or ever made any statement that could be so interpreted, and the observation is added: "The importance of sand filtration in getting rid of typhoid organisms in water-supply is so well established as to be beyond question."

Complexions and Insanity.—Mr. Hobart Langdon, writing on this subject, says that only 3% of the total number of insane people have light hair, and only 2% have blue eyes. His figures are obtained from 68 asylums located in various parts of the United States, Canada, and England. The total number of patients in these institutions was 16,512, of whom 703 had light hair, and only 66 red hair or auburn locks. In other words, 96% of the inmates were brunettes, with either black or brown hair. In one asylum in New England there was not a single inmate that was not a brunette. He makes no attempt to account for this peculiar fact, but asserts that it certainly looks as though blonds were less liable to insanity than those with darker hair or eyes. A peculiar feature was that the percentage of those regarded as incurably insane was much greater among the blonds than the brunettes. The total shows that among the dark-haired inmates only 50% were marked hopelessly insane, while among the blonds 81% were put in this category, and that only 3 among the red-haired patients escaped the same classification.

Miscellaneous.—The Tristate Medical Society of Iowa, Illinois, and Missouri will meet in St. Louis, June 15, 16, and 17. An interesting program is being prepared, and some of the most distinguished physicians and surgeons of the country will attend the meeting.—The New York School of Clinical Medicine: At the meeting of the medical board held April 9, Dr. J. L. Adams was elected secretary of the school, and preferences were conferred upon the following: Mental diseases, Dr. E. C. Dent, Superintendent Manhattan State Hospital West, Ward's Island; internal medicine, Dr. William Brewster Clark; gastrointestinal diseases, Dr. Robert Coleman Kemp, Associate Professor Graham Rogers; hydrotherapeutics, Dr. Alfred W. Gardner; ophthalmology and otology, Dr. George Ash Taylor; pediatrics, Associate Professor H. F. Sentfner; clinical instructor and assistant, Dr. William E. West; genitourinary diseases, Chief of Clinic and Associate Professor C. Stern; dermatology, chief of clinic and instructor L. D. Weiss.—New York: Dr. Warren L. Babcock, chief surgeon at the State Soldiers' Home Hospital, at Bath, N. Y., announces that he will resign his position at the Home on May 12, to accept the Superintendency of the Grace Hospital, Detroit, Mich. The plans for the new hospital which is to replace the old Fordham Hospital in The Bronx have been filed. The new hospital will be five stories high and fireproof, and will have a frontage of 121 feet and a depth of 43 feet, with a four-story extension 92 x 35 feet. The cost of the group of buildings is estimated at \$560,000 in round numbers.—Philadelphia: Wills Hospital Ophthalmic Society will hold a meeting May 9, 1904, at 8.15 p.m. The main subject chosen for discussion is affections of the lacrimal apparatus. Physicians interested in ophthalmology are cordially invited. The American Climatological Association will hold the twenty-first annual meeting in the banquet room of the Aldine Hotel, Chestnut street above Nineteenth, Philadelphia, on June 2, 3, and 4, 1904.—American Proctologic Society: The sixth annual meeting will be held at Seaside House, Atlantic City, N. J., June 8 and 9, 1904.

EASTERN STATES.

Suggestive Vital Statistics.—The Annual Report of the Board of Health of Connecticut contains some interesting facts. One of the most striking tables shows the steady and rapid decrease of tuberculosis in that state. The table covers

a period of 20 years during which, notwithstanding an increase in population from 622,700 to 908,420 by the last census, the annual deaths from tuberculosis fell from 1,505 to 1,356. Based on the numbers estimated of population the deathrate per 10,000 of population fell during the two decades from 23.2 to 14.9, or a reduction of 38.8%. As distinct from tuberculosis, pneumonia shows a rapid increase, and now heads all in mortality. In 1903 there were 1,428 deaths from this cause as compared with 1,317 from tuberculosis. The decrease of typhoid fever is assigned to the systematic effort of purification at the source of disease. He criticises severely the common tendency of treating measles and whoopingcough as trivial. The birth returns continue to indicate the slow and steady extinction of the purely native race, births from American born falling in 10 years from 8,487 to 8,283; while the births from foreign and mixed parentage rose during the same time from 11,467 to 12,576.

NEW YORK.

Why They Fought the Bill Abolishing the Coroner's Office.—In opposing the bill which legislates the coroners out of office and creates a bureau of medical examiners under the supervision of the Health Department, W. M. K. Olcott, at a public hearing recently by Mayor McClellan, declared that the measure had been drawn by the medical societies and that one of its purposes was to furnish more bodies for the medical laboratories of that city.

Epidemic of Measles in New York.—Officials of the Health Department report an alarming spread of measles. Many cases have proved fatal, being followed by pneumonia. The department's weekly report shows, in the five boroughs of Greater New York, 1,630 cases of measles, with 37 deaths due directly thereto, and 135 deaths from pneumonia. Physicians attribute the existing conditions to the severe winter, which caused living rooms to be kept tightly closed at the expense of ventilation.

Grand Lodge of Masons and Sanatorium for the Tuberculous.—At the meeting last week of the Grand Lodge of Masons, a project for the erection and endowment of the Masonic sanatorium for the tuberculous, under the auspices of the fraternity in New York State, was considered. The project is yet in an embryo state, although steps are being taken by the Masonic Sanatorium League to collect a fund as a nucleus for the purpose of establishing and endowing the sanatorium. If the project receives the endorsement of the Grand Lodge, active measures will be taken for its accomplishment.

PHILADELPHIA, PENNSYLVANIA, ETC.

State Board of Medical Examiners of New Jersey.—Examinations will be held at Trenton, N. J., June 21 and 22. Application for the regular blanks should be made before June 11.

Spotted Fever.—Not only has this disease been reported at League Island, Philadelphia, but also in Trenton there has occurred the first case in 40 years; two additional cases are reported as having occurred in Bordentown, N. J.

Baby Farm Investigations Show Children Were Destroyed by Quicklime.—Newborn infants are destroyed by quicklime in lying-in establishments, according to the latest revelations made to the coroner in his investigation into the conduct of these places.

Cerebrospinal Fever Reported at the Navy Yard.—Spinal meningitis has broken out among the sailors in the camp at League Island, and the alarm lest it spread is giving the physicians and the men much concern. Three men are down with the disease. The Bureau of Health was notified recently. Precautionary measures have already been instituted by the naval physicians, who have isolated the afflicted men.

War against Unlicensed Physicians.—The action taken by the County Medical Society and the State Board of Medical Examiners in waging war against unlicensed practitioners in the city of Philadelphia is meeting with the hearty support and cooperation of the entire profession in the city and State. Several arrests have been made and prosecutions instituted, others will doubtless follow, as these organizations are thoroughly in earnest in their desire to purge the community of these illegal practitioners.

Sanitary Affairs at League Island.—A further inspection of sanitary conditions at the League Island Navy Yard was begun a few days ago by a board of naval medical officers appointed by Surgeon-General Rixey, of the Navy, who made a personal inspection last week. The men on the board are Medical Director T. H. Streets, of the Naval Home; Surgeon H. G. Beyer, from the department at Washington, and Surgeon J. D. Gatewood, of the training ship Yankee. They were accompanied on the inspection by Drs. Biddle and Norton, who are stationed at the yard. The outbreak of cerebrospinal meningitis among sailors at League Island last week has caused much concern among the officials at Washington, and every possible effort is being made to find the source of the disease and perfect the sanitary condition of the yard.

SOUTHERN STATES.

To Prove the Mosquito Theory.—Information from New Orleans states that Dr. Frederic Forralbas is there from Havana, with a cage full of mosquitos of the variety which it is claimed propagate yellow fever. He is taking them to the St. Louis Exposition, where they are to be used in demonstrating the mosquito theory. The exhibit will renew itself and will be one of the interesting features of the Health Department. Dr. Forralbas believes that the results will be a general admission of the mosquito theory, doing away with quarantines.

Physical Examination for Candidates for the Naval Academy at Annapolis.—The *Army and Navy Register* for April 30, states that arrangements have been made at the Naval Academy for the special physical examination of candidates otherwise qualified for admission to that institution. This is the result of a report which has been made by Medical Inspector Howard E. Ames, on duty at the Naval Academy. He has pointed out the necessity of special precautions in the examination of candidates to the end that there may be excluded from the academic course those who are not up to a very high physical standard. He has pointed out that the present requirement of height with age is too low; that insufficient attention is given to the question of weight; that "vision is a subject that is treated in the slightest manner"; that defective hearing is still another trouble that is constantly waived; that the mouth with its appendages, particularly the teeth, is almost overlooked; that the grave defect of heart trouble is repeatedly waived. The Navy Department, acting on the advices from Annapolis, has decided this year to increase the physical requirements of candidates in the hope that the standard may be increased. Consequently, a special board has been detailed to conduct the examinations, composed of Medical Director John C. Wise, who is a member of the naval retiring and medical examining board in Washington; Surgeon William C. Braisted, on duty at the naval hospital at New York, and Passed Assistant Surgeon T. D. Myers, retired, who is on special duty in Philadelphia and in Washington.

WESTERN STATES.

Pneumonia Decreasing in Chicago.—Chicago's Bulletin of the Health Department for the week ended April 23, says: The pneumonia mortality has already broken all April records. During the first 23 days of the month 403 deaths were reported—a daily average of 22.1. The April daily average for the previous 14 years had been 12.4. For the current month the daily deaths from pneumonia have been 78% higher than usual.

Accident Statistics in Chicago.—An analysis of the 10,707 accidents recorded last year in Chicago is presented in a report just submitted by the Civic Federation. The largest number of accidents from any one cause, it was found, was under the head of "run over or struck by street cars," with a total of 457. Next, despite all the track elevation in the city, came accidents from railway trains or engines, with a showing of 446. In consequence of street cars striking wagons, 442 injuries were caused.

Efficient Work of the Dairy Inspectors in Chicago.—Chicago's Bulletin of the Health Department for April 23, says: The Dairy Inspector has examined during the last two weeks about 45 dairies in the immediate vicinity of the city. Of these 13 have been abolished on account of exceedingly insanitary conditions, and the work will be continued until all these places have been cleaned up. A milk inspector detailed to examine restaurants has made an inspection of the sanitary condition and also taken samples of milk and cream in all of the small restaurants on S. State and Clark streets from the river to Thirty-fifth street. Many of these restaurants were found to have filthy kitchens and a number were found selling milk and cream below grade. The usual 10 days' notice in which to comply with the sanitary regulations concerning the keeping and handling of milk and cream was given and a copy of the ordinance was left at each place. Those who do not comply with these regulations will be sued at the expiration of the notice. The war on the dirty milk can is being kept up. Any dealer who has filthy cans in his possession will be fined and advertised in the papers. Dealers have been notified that the ordinance requiring shipper's cans to be returned to farmers clean and dry within 36 hours will be rigidly enforced and all rusty cans will be destroyed wherever found. Vessels used in the handling of milk must be scalded or sterilized daily. All milk bottles must be sterilized in boiling water or steam, after being thoroughly washed.

CANADA.

Canada Sanatorium.—The first Government Sanatorium in Canada has just been completed at Kentville, N. S., and will be ready to receive patients about July 1. The location is in the Annapolis valley, 70 miles from Halifax, at an elevation of 400 feet, in a locality famed as a health resort, being a part of what is known as the garden of the province. The cost of the buildings, without furnishings, has been \$20,000. It will accommodate 20 patients.

Esquimaux Almost Exterminated by Measles.—News from Winnipeg, under date of April 28, says: All the Esquimaux living in the Mackenzie basin except ten families have been killed by the ravages of measles. Before the epidemic there were 40 or 50 families, or 200 or more persons.

FOREIGN NEWS AND NOTES

GENERAL.

Decrease in Typhoid Fever in Paris.—In 1882 the deaths from typhoid fever in Paris were 142 per 100,000 inhabitants; today the proportion is only 10 per 100,000.

Typhoid Fever in the Russian Army.—Recent information from London states that: A dispatch to the Standard from Kieff says it is stated in military circles there that 10,000 soldiers are in hospitals in Manchuria, chiefly typhoid patients.

Beverages and Cancer.—Dr. Alfred Wolff discovers that all the districts of high cancer mortality are districts in which beer and cider are largely drunk. Bavaria, for instance, heads the list in Germany, and Salsburg in Austria—both great beer drinking provinces. In France the statistics are still more striking. There is the most marked contrast between the high cancer mortality in beer drinking departments and the low deathrate from cancer elsewhere.

Race Suicide.—According to reports from London it appears that a controversy has arisen between Bishop Ripon, who delivered a discourse calling attention to race suicide in London and European countries, and Mr. Henry James, who takes the position that the falling off in the birthrate shows that people are beginning to think for themselves. He holds that it is the ultimate satisfactory solution of all of our social troubles and labor conditions. The large families of the working class are an inexorable burden and the overstocked labor market leads to poverty, degradation, and crime. Dr. Taylor, president of the British Gynecological Society, and a scientist of European reputation, points out that the birthrate of the United Kingdom from 1874 to 1878 was 34.3 per 1,000; from 1894 to 1898, 29.1 per 1,000, and in 1901, 28. The decline was greater than in any European country. There are 500 births a week fewer in London than 20 years ago.

OBITUARIES.

Abram Miller Henkel, from Bright's disease, at his home in Staunton, Va., April 19, aged 61; a graduate of the University of the City of New York in 1867, since which time he practised continuously in Staunton. He was a member of the Virginia State Medical Society, the American Medical Association, the National Association of Surgeons, and attending physician to the Wesleyan and Lutheran female schools, and a member of the Wesleyan State Hospital Board. He was a widely known and much esteemed physician.

Charles Kerr, at his home in Springfield, Ill., April 13, aged 66; a graduate of the Rush Medical College, Chicago, in 1865; was an army surgeon in the Federal service during the Civil war; member of the American Medical Association and one time member of the Iowa Legislature.

Edward J. McGorrick, at his home in Des Moines, April 16, aged 69; a graduate of the medical department of St. Louis University in 1855. He served as an army surgeon in various military divisions during the Civil war and was one time surgeon-general of Iowa.

Louis Drescher, at his home in Newark, N. J., April 27, aged 84. He was educated in Germany and came to the United States about fifty years ago. He retired from medical practice several years ago and thereafter devoted his time to inventions.

Oscar H. Huntley, from pneumonia, at his home in Buda, Ill., April 18; a graduate of Jefferson Medical College in 1856; surgeon in the Confederate service during the Civil war and one of the oldest practitioners in Bureau county, Ill.

Edward L. Randall, from pneumonia, at his home in Knoxville, Tenn., April 18, aged 50; a graduate of Missouri Medical College, St. Louis, in 1869. Dean and professor of theory and practice of medicine in Knoxville Medical College.

Changes in the Medical Corps of the U. S. Army for the week ended April 30, 1904:

HUNTINGTON, First Lieutenant, **PHILIP W.**, assistant surgeon, will proceed to Sorsogon, Sorsogon, for duty, relieving First Lieutenant **William R. Eastmann**, assistant surgeon, who will proceed to Manila for instructions.

HOGAN, DAVID D., contract surgeon, will proceed to Silang, Cavite, for duty, relieving Contract Surgeon **Joseph W. Reddy**, who will proceed to Manila, P. I., for instructions.

HANNER, First Lieutenant **John W.**, assistant surgeon, will proceed to Camp McGrath, Batangas, for duty, relieving Contract Surgeon **Charles F. Kuhn**, who will proceed to Camp Gregg, Pangasinan, for duty.

KULP, Captain **JOHN S.**, assistant surgeon, is assigned to duty as commanding officer, company of instruction, hospital corps, No. 2, Fort McDowell, to date March 30.

HOWELL, First Lieutenant **PARK**, assistant surgeon, will proceed from Fort McPherson to Fort Screven for temporary duty, to enable First Lieutenant **Harry L. Gilchrist**, assistant surgeon, to comply with orders. Upon arrival of First Lieutenant **Reuben B. Miller**, assistant surgeon at Fort Screven from leave, First Lieutenant Howell will return to his proper station.

LITTLE, First Lieutenant **WILLIAM L.**, assistant surgeon, is granted leave for 21 days, to take effect as soon after June 5, 1904, as his services can be spared by his post commander.

CHAMBERS, WILLIAM H., contract dental surgeon, with his enlisted assistant, will be relieved from temporary duty at Camp George H. Thomas, and will proceed with his assistant and dental outfit to Atlanta, Ga., and report at headquarters for duty until May 1, retaining station at Fort McPherson.

GOFF, A. P., contract surgeon, leave granted January 6 is extended one month.

ANDERSON, EVERETT A., contract surgeon, will report to the commanding officer, eleventh cavalry in camp, Presidio, to accompany a detachment of that regiment to Fort Riley and Jefferson Barracks, and upon the completion of that duty will proceed to his home, Devil's Lake, N. D., for annulment of contract.

ALBRIGHT, CHARLES W., and MANSEAU, OSCAR A., sergeants first class, now with company of instructions, hospital corps, No. 2, Fort McDowell, will report to the commanding officer eleventh cavalry in camp, Presidio, to accompany detachments of that command to Fort Des Moines and to Fort Sheridan, respectively, and upon the completion of this duty these soldiers will avail themselves of the furloughs granted them, reporting upon expiration of furlough at Fort McDowell for duty.

PATTON, First Lieutenant IRVINE W., assistant surgeon, will report not later than April 29 at Fort Jay for temporary duty with the troops going to Sea Girt, N. J. The commanding officer of Fort Wadsworth will direct Contract Surgeon George F. Adair to report at Fort Hamilton for temporary duty at that post to relieve Assistant Surgeon Patton. The medical officers will be returned to their proper stations when their services are no longer required.

WILCOX, Colonel TIMOTHY E., assistant surgeon-general, retirement from active service, April 26, 1904, by operation of law under the provisions of the act of Congress approved June 30, 1882, is announced. Colonel Wilcox will proceed to his home.

GREGORY, VERDO B., contract surgeon, will proceed to Atimonan, Tayabas, for duty, relieving Contract Surgeon Elias H. Porter, who will proceed to Binangonan de Lampon, Tayabas, for duty at that station, and in addition to these duties will attend the sick at Baler and Casiguran, Tayabas. Contract Surgeon Wallace E. Sabin will proceed to Candon, Ilocos Sur, for duty.

ARTAUD, FRANK E., contract surgeon, will proceed to Ilagan, Isabela, for duty.

TIGNOR, EDWIN P., contract dental surgeon, is granted leave for 15 days, from about April 30.

CRABTREE, First Lieutenant GEORGE H., and CONNELLAN, JOHN J., sergeant first class, are detailed for duty in connection with the Military Athletic Tournament, Madison Square Garden, New York city, which commences May 2.

MASON, Major CHARLES F., surgeon, is granted leave for four months, from about June 1.

Changes in the Public Health and Marine-Hospital Service for the week ended April 28, 1904:
